DR. JOSEPH COLLINS was also inclined to think that the case was one of rheumatic multiple neuritis. Acromegaly, he said, was really a uniform enlargement of the joints—a condition which the photographs and skiagraphs showed did not exist here. The hands and feet were misshapen, as might occur in rheumatic arthritis. The condition of the heart also favored the view that the case was rheumatic.

DR. B. SACHS said that while the case was certainly atypical, the increase in stature in recent years and the peculiar shape of the lower jaw seemed to him to point rather strongly to acromegaly. There was not a thickening of the lower jaw, but an actual prolongation of the ramus of the lower jaw. The diagnosis of a rheumatic affection did not entirely cover all of the facts in the case.

DR. HIRSCH said that in his opinion, the skiagraphs showed clearly that the joints themselves were perfectly normal although the ends of the bones were somewhat thickened. That in itself should exclude joint disease. Again, the marked swelling of the thyroid was not compatible with the rheumatic theory. What was the most characteristic of all was the increase in the lateral diameter of the foot. As the nerves were involved in acromegaly at times, it was quite proper to look upon the neuritis as having the same origin. As there had only been about one hundred cases in all reported one was hardly warranted in speaking of acromegaly as being "typical."

AMAUROTIC FAMILY IDIOCY.

DR. FREDERICK PETERSON presented a child fifteen months old, the only child born of a Hebrew mother when she was nineteen years of age. The pregnancy had been normal and the labor difficult and instrumental. There had been slight asphyxia at birth. The child had been nursed until two months ago. It had been well up to the age of five months when it had had some fever, and shortly afterward had developed a very painful condition of the cervical spine. The case had been sent to the nervous department of the Vanderbilt Clinic by Dr. Gibney. The arms and legs had been somewhat rigid; the head muscles also rigid. The child was nearly blind, and the disk showed a typical white atrophy with the cherry-red spot. The strange feature of the case was its apparent commencement as a meningitis.

DR. V. P. GIBNEY stated that he had examined the child and had failed to find anything orthopedic about it.

DR. TERRIBERY said that he had obtained a history of the child having been severely injured by instruments at birth, and the mother had called attention to a scar in the frontal region, and had stated that the attending physician had thought this injury so severe that he had doubted if the [illegible]ld survive. According to his recollection the mother had told him that the trouble had begun much sooner after birth than had been stated in the history just given.

DR. SACHS said that there was no reason why a child with amaurotic family idiocy should not have an acute cerebral disturbance, and hence, the acute symptoms detailed would not militate against the diagnosis. The ophthalmoscopic picture confirmed this view.

DR. HIRSCH said it was especially worthy of note that there was still some vision remaining, as some authorities had reported cases of this kind in which the children had been born blind. He had examined one of these cases anatomically and had come to the conclusion that he had had to deal not with an arrest of development, but with an acquired disease. The case just presented afforded additional support to this view.

DR. PETERSON said that he had carefully inquired into the history, and had been told by the father that the child had been apparently healthy up to the age of five months, or until the illness marked by fever and croupy cough. The marked retraction of the head and the great tenderness in this region had been so great as to lead a good pediatrist and a surgeon into the belief that there was some serious injury—probably a dislocation of the cervical vertebra. There was typical white atrophy present. The child's general health was failing.

CASES OF RIGID SPINE.

DR. JOSEPH COLLINS presented a man, forty-five years of age, who had served in the German army. About ten years ago the present trouble had gradually developed —the bending of the back and the difficulty in moving one hip. Examination had shown a cessation of abdominal respiration and a rigidity of the spine.

DR. V. P. GIBNEY showed a similar case, that of a man, thirty-five years of age, who for the past five years had been stooping a good deal. About seventeen years ago he had had an attack of gonorrhea lasting three or four weeks, and involving the lower extremities. Four years later he had had an attack of sciatica on the left side, lasting nearly a year. In October of 1896 there had been much pain in the heel extending up into the hips.

DISCUSSION ON CHRONIC PROGRESSIVE RIGIDITY OF THE SPINE WITH ANKYLOSIS.

DR. B. SACHS opened the discussion. He said that in 1892 a paper on this subject had been published in a Russian journal by von Bechterew. The symptoms were immobility, complete or partial, of the whole spinal column, without any distinct tenderness on percussion; a

paretic condition of the muscles of the head, trunk, and extremities, and a diminution of sensation within the distribution of the cutaneous branches of the nerves supplying the back and the lower cervical plexus; paresthesia and pain in the back, neck, extremities, and vertebral column. All other joints had remained exempt in spite of the progressive character of the disease. Traumatism and hereditary influences were supposed to be the chief etiological factors. Strümpell in 1884 had very properly called attention to these cases in a chapter on chronic rheumatism, The chief difference between the descriptions given by these two authors were in the implication of the hip-joints and the entire absence of spinal root symptoms in the type described by Strümpell. Marie had also described the malady under the name of *spondylose rhizomelique*. In some of the cases described there was a superficial resemblance to arthritis deformans. Von Bechterew, in a post-mortem examination made on one of the first patients described, had found a chronic leptomeningitis in the upper cervical region compressing the spinal roots. The degeneration of the spinal roots was supposed to have been due to changes in the nerve cells. The gray matter of the cord was not diseased. He had been surprised to find no primary lesion of the vertebra or joints. Maria had studied a skeleton in which there was marked proliferation about the lumbar vertebræ, and the bones entering into the formation of the hip-joint, and inferred that ossification of the ligaments must have caused the complete immobility of the spine. The von Bechterew type was characterized by chronic rigidity of the spine, often limited to the cervical region, a chronic leptomeningitis with root and spinal-cord changes, and without vertebral joints being affected. In the Maria type there were no root symptoms, but ossification of the ligaments, hypertrophy and ankylosis of the joints.

The following cases were then reported:

Case I.—A man at the Montefiore Home whose present illness had begun about six years ago had pain in the left knee upon rising, increasing on attempting to walk. The pain had continued for a year and a half, when he had entered the Presbyterian Hospital. He had been temporarily improved while there, but one year later had entered the Montefiore Home. For the first eighteen months there he had had a persistent cough, but no evidence of tuberculosis. Under narcosis all of the affected joints had remained rigid and during the anesthesia there had been a marked ankle-clonus. The case corresponded very closely with the Strümpell–Marie type.

Case II.—A Russian, male, fifty-three years of age, with a completely negative family history. He had been married twenty-five years, and had five healthy, living children. He was a well-nourished and well-preserved person. The lower part of the spinal column and the hips were bound together. His case also was of the Strümpell–Marie type.

Case III.—A man, forty-eight years of age, a Russian tailor. His present illness had begun two and a half years ago with pain in the sacral and lumbar regions, without any history of trauma. Six year ago he had had pains in the right shoulder and forearms supposed to be rheumatic. The man was tall and well-nourished. He bent forward to the left, and had a spastic paretic gait. The knee-jerks were lively and ankle-clonus was present on both sides. There was a distinct tenderness of the twelfth dorsal vertebra, and this was increased lower down. On March 2d of the present year it had been noted that the patient was worse, the lower extremities being contracted. On attempting to stand erect the whole body was curved. The lower portion of the vertebral column was twisted, and he dragged the left lower extremity. In view of this sudden development of root symptoms, increase in pain and loss of the left knee-jerk, possibility of a neoplasm compressing the nerve-roots had been considered. A laminectomy had been done on him by Dr. A. P. Gerster and a portion of the thickened laminæ and enormously thickened lining membrane removed. Portions of the first and second lumbar vertebræ were also removed. This thickening of the membrane might give some hint to the character of the morbid process—at least it had suggested that the operation was responsible for the decided improvement that had occurred since that time.

Case IV.—A man, fifty-four years of age, having a negative family history. He had had an attack of acute articular rheumatism. Three years ago the present trouble had begun with pain across "the small of the back." He had gradually come to walk stiffly. He had been given a thorough course of iodids, with the result that there was now very much less rigidity than last spring. The diagnosis of a specific or rheumatic pachymeningitis seemed to be the most plausible one, and the case was presented simply to show a form of secondary ankylosis.

The speaker said that von Bechterew type must be looked upon as one of secondary rigidity. Ordinary rheumatic affections occur equally in the two sexes, whereas, with but one exception, the reported cases of spinal rigidity had been in males. Comparison of the pathological conditions showed that in rheumatism the affection of the ligaments was secondary. The differences between arthritis deformans and the type under discussion were not so marked.

Dr. Fraenkel said that the chief question to decide was whether there was any pathological relation between the Strümpell type and cases of chronic rheumatism or arthritis deformans. Of course, chronic rheumatism would give rise to a stiff back, but there would not be the clinical symptoms emphasized in the paper just presented.

Dr. Gibney said his attention had been called to the subject about eighteen years ago by a case of spondylitis deformans, and since then he had been trying to differentiate the many varieties of stiff back coming under his observation. He had seen a number of cases of senile arthritis.

Dr. C. L. Dana said that he had been taught that there were two types of arthritis deformans, *viz.*: (1) The type beginning in the small joints and progressing steadily, and (2) the senile type, beginning in the back and

hips, and stiffening them. There were almost always some cases of that kind in Bellevue Hospital. He had studied his own cases in connection with those reported by others, and had come to the conclusion that the cases of the Strümpell-Marie type were nothing more than arthritis deformans. He felt sure that, in due time, cases would be found in which the spine only was affected, and in which only the root-joints were affected. He now had a case in which only the hips were affected, the spine not having been involved as yet. He did not personally feel that either Strümpell or Marie had added anything at all to the clinical knowledge of these cases. Twenty-five years ago it had been stated very clearly that rheumatoid arthritis sometimes presented this particular form. Von Bechtereff had certainly described types that were distinctly secondary; the case reported with autopsy seemed to him one of specific meningitis. There was a type of stiff spine which had been described by Dr. Bradford of Boston, and proved by him to be due to gonorrheal rheumatism. In this case the history was most conclusive. He now had under observation a very bold kyphotic spine in which there seemed to him but little doubt that the case was rheumatoid arthritis. He, therefore, believed that *spondylose rhizomelique* was a nosological superfluity.

DR. GEORGE R. ELLIOTT said that three years ago he had been privileged to examine under ether, with Dr. Fraenkel, one of the patients presented that evening, and had found that the rigidity had remained. Since that time the case had proved to be a classical type of spondylose rhizomelique of the Strümpell-Marie type. He was not yet willing to admit that we were dealing with a disease *per se*. That it was not arthritis deformans admitted of little doubt. It had been said that this type could be differentiated from arthritis deformans in that the latter affected chiefly the small joints, but he believed such a statement must be modified. A clinical examination of so-called arthritis deformans revealed two distinct findings, *viz.:* one, an atrophic process, in which, after acute or subacute symptoms, the joint got smaller, and a second clinical picture in which the joints became hypertrophied. Pathological study supported the clinical findings. He could see nothing in either the clinical history or in the pathological study of the type presented which differed from the hypertrophic form of the smaller joints. He was of the opinion that there were two distinct diseases—arthritis deformans and a proliferating arthritis. This might be called the Strümpell-Marie type, or better, central type of the proliferating kind, as distinguished from the peripheral type of the proliferating kind, but it was not to be confounded with arthritis deformans proper. That the small joints always escaped, as had at first been held, was not true. Marie himself had reported affection of small joints in one of his cases. This statement is supported by Bannatine of England and Goldthwait of Boston. There was much about the type of disease under discussion to suggest a degeneration, *viz.*, gradual destruction of soft parts of joint and partial replacement by osseous material, the parts becoming welded together with very little excess of tissue or deformity. The proliferation, which was slight, appeared as a secondary process, the result of irritation. It was very unlike that producing so-called arthritis deformans proper. It was not so rare as might be supposed from the few cases so far reported. Dr. Goldthwait had reported, at the last meeting of the American Orthopedic Association, ten cases which had come under his observation. So marked a type as one of the cases just presented was rare indeed; it was a classical example of the Strümpell-Marie or central type.

DR. W. R. TOWNSEND said that he had at present under his care a child presenting a picture very closely resembling arthritis deformans. If he remembered correctly Charcot had insisted that these cases were not rheumatic but neurotic. He had seen a number of cases of rigid spine, and had supposed them to be either rheumatic or of the types of arthritis deformans of the neurotic character described by Charcot.

DR. COLLINS said that a discussion of this kind could not be profitably carried on until the various conditions spoken of had been clearly differentiated. He then reported two cases occurring in women. The first case was a woman of thirty years, first seen in the City Hospital last spring. She had been well up to the fall of 1897, at which time she had had what she called "a stroke on the left side." In August, 1898, she had begun to complain of pain in her back, and she soon became so stiff that she could not get around. Examination had shown over the sacrum what had at first appeared to be a bony tumor of the sacrum. There had been no atrophic cutaneous disturbances although she had been on her back for a long time. There were no sensory disturbances of the legs. The right upper extremity was stiff at the shoulder-joint. There was no evidence of cranial nerve palsy. She had died about four weeks later. At the autopsy it was noted that the stiffness in the hip-joints was not so great as during life. The liver showed marked passive hyperemia. The kidneys showed cloudy swelling. The heart showed marked fibrous endocarditis and advanced myocarditis—a cartilaginous myocarditis, and ossification of the fibers and fatty degeneration. The brain and spinal cord had been stained and examined, but had appeared to be normal. The vertebral column seemed to be made of one piece, and this was due entirely to the calcification of the anterior spinal ligament, the posterior spinal and the interspinal ligaments. The intervertebral disks were not thickened. The change in the hip-joints was comparatively slight. The shoulder-joint was not examined. The changes, therefore, were not those of an inflammation—nothing like an ordinary rheumatism. The speaker said that cervical meningitis would produce a stiff back and a stiff neck—a symptomatic stiff back, and it seemed to him this was the character of von Bechterew case.

DR. PETERSON said that he had seen three or four cases, all of which he had diagnosticated as arthritis deformans of rheumatic origin. One of these patients, a man of forty, was of a neurotic temperament, and had been previously under the care of a number of specialists. He had developed in the course of the preceding three or

four years an almost complete immobility of the spine and stiffness of the hips and knees. There was no enlargement of the small joints of the hands and feet, and no evidence of cardiac disease. If cases of this type were excluded, as Dr. Collins had suggested, there would be very few left. What Dr. Collins had found at autopsy seemed very much like what had been observed in many cases of arthritis deformans of the rheumatic type.

DR. SACHS, in closing, remarked that the case described by Dr. Collins seemed to be rather acute as compared with those that had been reported. The post-mortem findings corresponded closely with some von Bechterew had reported. The von Bechterew type had been brought into the discussion because it had been necessary to differentiate it from the others, and for this reason he had endeavored in the paper to show more clearly than previous writers that von Bechterew's case was of the secondary type. The morbid changes were quite different in the two types. In the European journals there had been much opposition to the view that they were at all closely allied to rheumatism or to arthritis deformans.

REVIEWS.

A TEXT-BOOK OF PHARMACOLOGY AND THERAPEUTICS, OR THE ACTION OF DRUGS IN HEALTH AND DISEASE. By ARTHUR R. CUSHNY, M.A., M.D., Aberd., Professor of Materia Medica and Therapeutics in the University of Michigan, Medical Department. Philadelphia and New York: Lea Brothers & Company, 1899.

IF supplemented by the study of a guide to practical therapeutics this work will afford the student an excellent text-book on materia medica, written from the standpoint of pharmacodynamics and based on laboratory research. The therapeutic application of drugs is not neglected in the book, but the descriptions of their uses are molded to the findings of their physiological effects, *per se*. This volume is dedicated to Schmiedeberg, author of the "Grundriss der Arzneimittellehre," from which volume is derived much of the inspiration of the present work. Those who have known this teacher's work will appreciate more fully the philosophic grasp that the pupil displays.

Many features of the work are very commendable. Drugs that are little used are passed over with praiseworthy brevity, while the chapter on organic remedies, though by no means exhaustive, is ample and modern. The bibliographies attached to the different subjects may have little value to the student, but to the practitioner and investigator they will prove of considerable service.

DIE KRANKHEITEN DER EIERSTOCKE. (THE DISEASES OF THE OVARIES AND THE PAROVARIUM.) Herausgegeben von Professor Dr. A. MARTIN, Griefswald. Leipsic: Arthur Georgi, 1899.

THE two volumes comprising this portion of Martin's work on the diseases of the uterine adnexa deal with the ovarian and parovarian inflammatory and neoplastic conditions. The anatomy and physiology of the ovary are first discussed together with a terse description by Martin of the palpation of the ovary. Developmental defects, and the inflammatory ovarian disturbances are next considered and are followed by a chapter on the infectious granulomata affecting the ovary, syphilis, actinomycosis, tuberculosis and leprosy. The various ovarian tumors with their complications are then dealt with. The special pathology of the tumors, a long chapter on treatment, and a consideration of the anatomy of the parovarium and its pathology bring the work to a close.

It is dificult in an exhaustive work of this kind to select portions for special review. Striking elements are the vast abundance of material studied, and thorough consideration given to pathological--especially to microscopic--study of the material, the prominence given to the etiology of ovarian disease, and the excellent chapter on the therapeutics of the ovarian disturbances including a noteworthy study of women upon whom ovariotomy has been performed. The illustrations, entirely original, with rare exceptions, are numerous and supplement the text thoroughly. From the sketch of the work submitted, it will be seen that a detailed review is unnecessary. It is sufficient to say of it that as a contribution to the knowledge of ovarian disease it marks a distinct advance over any recent publication. Professor Martin's fellow contributors are Heinrichs, Herter, Kippenburg, Kossman, Orthmann, Sanger and Stocklin, Wendeler and Wilms. The giant's share was done by Martin himself.

MATERIA MEDICA, THERAPEUTICS AND PHARMACOGNOSY. By FINLEY ELLINGWOOD, M.D., Professor of Materia Medica in Bennett Medical College, Chicago. Chicago: Medical Press Co., 1899.

THIS is a long exposition on the eclectic method of the treatment of disease by drugs, the classification resting entirely upon the clinical effect of the agents employed. There is a superabundance of botanical lore and not enough of physiological action for a model text-book. The book-making and paper are exceedingly poor.

THERAPEUTIC HINTS.

Disinfectant Powder for Cervical Cancer.—

℞	Iodoformi	ʒ iv
	Quininæ sulphat.	gr. xlviii
	Pulv. carbonis	ʒ i
	Ol. menth. piper.	gtt. x.

M. Sig. Apply on tampon to cervix.—*Gilette.*

Sedative Action of Methylen-blue on Insane Patients.—BODONI reports a number of cases of different forms of insanity in which he tried injections of this drug for conditions of excitement, with very satisfactory results. The treatment was regularly followed by general depression, frequently by sleep. That the drug acts as a vasoconstrictor was evidenced by pallor of the skin. No injurious effects were noted.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXV. NEW YORK, SATURDAY, DECEMBER 2, 1899. No. 23.

ORIGINAL ARTICLES.

THE HEMOSTATIC USE OF GELATIN: WITH REPORT OF A CASE OF HEMOPHILIA TREATED BY GELATIN; WITH RECOVERY.[1]

BY J. B. NICHOLS, M.D.,
OF WASHINGTON, D. C.

A THERAPEUTIC procedure that has been developed in France within the past four years consists in the utilization of the coagulating influence of gelatin upon the blood to secure hemostasis in hemorrhagic conditions and aneurisms. The fact that gelatin has a distinct and marked coagulating action on the blood was discovered by A. Dastre and N. Floresco, who made detailed experimental studies of the subject and reported their results to the Société de Biologie of Paris in February and March, 1896. Their discovery of the hemostatic properties of gelatin was first utilized therapeutically by Paul Carnot of Paris, who, in July, 1896, reported successful treatment of five cases of hemorrhage by the local use of gelatin. The first internal employment of gelatin recorded was made by Lancereaux and Paulesco, also of Paris, who, in June, 1897, reported successful results in the treatment of an aortic aneurism by subcutaneous injections. Since then this therapeutic measure has attracted attention in various quarters, though it has not attained widespread notice.

According to the accessibility of the point affected gelatin is used either locally or internally. As different methods are necessary and different conditions are presented, its employment in these two ways requires separate consideration.

1. *Internal Use of Gelatin.*—In cases where the seat of the hemorrhage or other lesion is not directly accessible, the hemostatic action of gelatin can be obtained only by introducing it into the circulating blood in the hope that at the affected point the desired result will be produced. Subcutaneous injection affords about the only practicable means of introducing the gelatin though rectal injection might also be of some utility. Intravenous injection would probably be too dangerous to be admissible and ingestion by the mouth is excluded, since the gelatin would be altered and its coagulant properties destroyed by the processes of digestion.

[1] Read before the Clinical Society of Washington, D. C., October 23, 1899.

As, in order to coagulate the blood, the gelatin must be present in sufficient quantity at the point affected, and as a greater amount of gelatin can be applied locally to an external bleeding point than can be brought to bear when introduced into the circulating blood, the local use of gelatin would apparently be more efficacious and certain than its internal use. For this reason, and in view of the danger in injecting gelatin, the local method is preferable whenever it is possible. Subcutaneous injection is to be employed only when, from the nature of the case, no other method of application is practicable; it is thus available in cases of internal aneurisms, or internal hemorrhages, like hemoptysis, hematuria, intestinal hemorrhage, purpura and the like.

As too great an increase in the coagulability of the blood might result in the formation of undesired intravascular clots, with possibly disastrous consequences, it is obvious that the introduction of gelatin into the circulation is not devoid of danger and not to be practiced carelessly. Gelatin may also exert a specific physiological action on the organism not as yet determined, which has to be taken into account. That the danger is real and not merely theoretical is shown by the fact that already in two fatal cases serious results are with greater or less probability attributed to the subcutaneous injection of gelatin. In one of these patients, that reported by Boinet, the clot which formed in the aneurismal sac pressed upon the pulmonary artery. This restricted the blood-supply to the lungs, and pulmonary tuberculosis subsequently developed; that the secondary development of tuberculosis in this patient can be properly ascribed to the gelatin has, however, been regarded as very doubtful, and the results were, at most, remote and indirect. In the other case that of Barth, the evil effects were perhaps more clearly due to the gelatin. This patient, a woman, with an aneurism of the arch of the aorta had received about thirteen subcutaneous injections of gelatin. Some days after the last injection, which consisted of 30 cubic centimeters of a two-per cent. solution, she was suddenly seized with dyspnea, syncope, and cyanosis, and died in collapse. At the autopsy the aneurismal sac was found filled with thick clots, which also extended beyond the sac into the left internal carotid artery.

A general agreement has not been reached with reference to dosage and administration. Lancereaux and Paulesco, basing their figures on experimental work and the results of treatment, recommend the use of a 2-per cent. sterilized aqueous solution of gelatin with .7 per cent. of sodium chlorid; of this 200 cubic centimeters is injected at a sitting; this is repeated at intervals of four to eight days until the aneurism is hardened or the desired effect is produced. Others have followed this dosage, while still others consider the amount too great. Huchard in a case of tubercular hemoptysis used a solution composed of gelatin 7, sodium chlorid 10, and water 1000 parts. The amount injected was 50 cubic centimeters. For aneurisms he employed a stronger solution, gelatin, 2; sodium chlorid, 10 (?); water, 100 parts, and began with a dose of 25 cubic centimeters and increased this to 50 cubic centimeters, the injections being made every two to five days. The gelatin used was of the best quality, such as the French gelatin commonly employed by bacteriologists.

It goes without saying that the gelatin solutions should be perfectly sterile, and that the injections should be made strictly aseptically. The solutions can be sterilized by heating at 100° C. for fifteen minutes daily for two or three days; and they then should be kept for a time to see if any growth develops in them. In sterilizing, too high a temperature (over 115° C.) should be avoided, in order to prevent deleterious changes in the constitution of the gelatin. The solution should be at the body temperature when injected. The injections are made in loose subcutaneous tissues, as in the abdominal walls or the buttock. Injection directly into the aneurismal sac has been suggested but not yet reported.

The details with reference to the dosage of gelatin for subcutaneous use, then, can not yet be regarded as finally settled. It is necessary on the one hand to employ sufficient amounts to produce the results aimed at, and on the other hand to avoid dangerous quantities. The degree of concentration of the solution is also an important point, in connection with the absorption of a substance with such physical properties as gelatin possesses. The absorbability of gelatin has been a subject of discussion. Calcium chlorid may prove to be the most useful ingredient to employ in association with the gelatin, instead of sodium chlorid, since the active coagulating power of calcium chlorid is now well known. Carnot, indeed, is extremely cautious as to the subcutaneous use of gelatin, preferring in its stead calcium chlorid, as being very efficient, safe, and capable of use by the mouth as well as hypodermatically. Ordinarily the injections of gelatin do not cause any material reaction or disagreeable consequences. At times, however, especially after the first or second injection, certain reactions may occur, which have been summarized by Deguy as follows: (1) fever, with slight rigors and insomnia, may follow for a day or two; or the injection may be followed at its site by (2) pain and tenderness, (3) a diffuse redness of the skin, or (4) induration.

The results reported from the subcutaneous injection of gelatin in various conditions are, briefly, as follows:

Aneurisms.—Lancereaux and Paulesco report results in five cases of aneurism. Two cases of aneurism of the arch of the aorta and one of subclavian aneurism were treated with succees, that is, a clot formed in the interior of the aneurismal sac, as shown by hardening, decrease in size, and cessation of pulsation of the tumor, together with relief of pain and other distressing symptoms and improvement of the general condition. In two cases of fusiform aneurism or dilatation of the aortic arch no benefit resulted. From this Lancereaux and Paulesco conclude that in fusiform aneurisms, in which there is no sac to favor coagulation, the gelatin treatment is not so efficient. Huchard of Paris treated two cases of aneurism, one successfully, the other unsuccessfully. Beck of New York reports treatment of a very large aortic aneurism with much improvement. Futcher of Johns Hopkins Hospital, Baltimore, reported treatment by this method of four cases of aneurism, three of the thoracic aorta, one abdominal, with improvement in one case, no benefit in two cases, death during treatment in one case.

Hemorrhages.—Huchard in a case of frequently recurring hemoptysis in a tuberculous patient employed gelatin injections, resulting in cessation of the hemorrhages. Lesage of Canada reports a case of habitual epistaxis and uterine hemorrhages treated by subcutaneous gelatin injections, with successful results. Hervieux of Canada reports a case of intestinal hemorrhage in typhoid fever, which had lasted four days, which yielded promptly to the injection of gelatin. Curschmann of Germany employed the subcutaneous method in fourteen cases of hemorrhage—six of gastric hemorrhage, six of pulmonary hemorrhage, one of typhoid intestinal hemorrhage, and one of hemorrhoidal bleeding, with cessation of the hemorrhage "remarkably soon" in thirteen of the cases. Arcangeli of Italy treated two cases of purpura hemorrhagica by this method, with "complete success." I find no report of hematuria (renal) treated, but gelatin might be worth trial in this condition. Jaboulay of France has suggested and practised the subcutaneous injection of gelatin prior to operations in which serious loss of blood is to be

expected, as in bleeders. He thus operated with marked results on a goiter and in an incision of a sarcoma of the breast.

2. *Local Use of Gelatin.*—The solution of gelatin mostly employed locally for the purpose of arresting hemorrhage consists of 5 to 10 per cent. of gelatin, with .6 per cent. to 1 per cent. of calcium chlorid or sodium chlorid, in 100 parts of water. This may be sterilized by heating to 100° C. for fifteen minutes daily for two or three days, avoiding a temperature much in excess of 100° C. The (10 per cent.) gelatin culture-medium used in bacteriological work can in case of need be melted and applied; pepton, which is ordinarily contained in this medium, has, it is to be noted, a distinct counteracting effect on the coagulating action of gelatin. If it is desired to make the solution antiseptic as well as sterile the usual antiseptics can be added, as .1 per cent. of mercuric bichlorid. Queyrat has suggested the addition of glycerin. When the gelatin solution is to be employed it is melted and brought just to the body temperature. It is applied by irrigation with, or injection of, a quantity, or by applying a tampon or compress saturated with it. The ordinary precautions as to asepsis are, of course, to be observed.

In addition to its hemostatic action it has seemed to some that the gelatin applied to a wound has a distinct nutritive action on the tissues and promotes the process of repair. This seems reasonable in view of the similar action claimed for the use of nutrients on wounds. On the other hand the gelatin affords a favorable culture-ground for bacteria in the wound or cavity affected; and to obviate this disadvantage, in cases where it is necessary to inject a quantity of gelatin and leave it for some time, as in intra-uterine injections, it has been recommended to add antiseptics like phenol or mercuric bichlorid, and not to leave the gelatin application too long. The use of gelatin in this manner is easy, and aside from possibly encouraging bacterial growth is perfectly safe and harmless. The method is available for use in all cases of hemorrhage, especially in hemophilia, in which the bleeding-point is accessible.

The conditions in which the local application of gelatin has been practised, and the recorded results, may be briefly summarized as follows:

Of epistaxis Carnot reports four, Siredey one, and Lesage two cases which promptly yielded to the gelatin treatment. Some of the cases were in bleeders, and were violent, persistent, and recurrent, and had resisted other treatment. In one patient with slight but continued bleeding from both nostrils following a blow on the nose I applied gelatinized tampons about four hours after the injury. The bleeding immediately ceased in one nostril, but continued in the other until the following day. Gaudier in three cases of removal of vascular tumors from the nasal fossa, followed by profuse and persistent hemorrhage, reports that the bleeding was easily checked by irrigating the bleeding-points with gelatin solution.

In gastric hemorrhages it has been urged that, on account of the action of the gastric juice, gelatin locally used would be inefficacious, but as this objection is based only on theoretical grounds it would seem that practical trial of the method would be worth making. Polyakoff reports a case in which hematemesis from a gastric ulcer, rebellious to other treatment, yielded immediately to the ingestion of 200 cubic centimeters of ten per cent. gelatin solution thrice daily.

In vesical hemorrhage, resulting from neoplasms of the bladder, Noguès reported treatment of four cases, without any favorable result.

Hemorrhoidal bleeding has been treated by local application of gelatin solution in three cases recorded by Carnot, Siredey and Lesage, with successful results.

In uterine hemorrhage the method has been employed, mostly by intra-uterine injections, also by gelatinized vaginal tampons, in thirty-two cases reported by Carnot (1), Siredey (9), Martin (1), Lachatre (20), and Bar and Keim (1). The hemorrhage was associated with chronic endometritis or metritis in fourteen of the cases, metritis with mucous polyp in one case; abortion, seven cases; fibroid tumors, six cases; cancer of the cervix, one case; laceration of vagina during labor, one case; menopause, one case; unknown cause one case. In all the cases except that due to menopause the treatment was successful and the hemorrhage definitely checked. Dalché also reports a case treated by gelatin in which a voluminous intra-uterine clot formed and caused much trouble, being expelled only with pain and difficulty.

In hemorrhage from superficial wounds Carnot and others have noted the efficiency of gelatin solutions locally applied by irrigation or by compress. Of course it would only be in exceptional cases of this kind, as in hemophilia or where ordinary means of hemostasis fail, that recourse to gelatin would be necessary.

I have had one case of hemophilia, in which profuse hemorrhage from an accidental wound ceased immediately upon the use of gelatin, which is here given in detail:

F. M., a dairyman, twenty-four years old, with a negative personal and family history and no history of hemophilia, on November 11, 1898, accidentally cut his right wrist and forearm on broken glass, ap-

parently while under the influence of alcohol, and was immediately brought to me. The wounds had bled very profusely and the patient was weak and excited. There were two wounds, one about four centimeters long on the anterior aspect of the right wrist, on the ulnar side, no tendons, large vessels, or nerves being found severed; the other about six centimeters long on the posterior ulnar aspect of the right forearm some eight centimeters above the wrist, in which an extensor tendon was partially divided. The wounds were cleaned, the divided tendon sutured with catgut, and the skin closed with horsehair; no vessels were ligated, bleeding being apparently checked by hot compresses.

The wounds were first redressed three days later, November 14th. They had been very painful and had bled freely into the bandages. On removing the dressings a jet of blood spurted at right angles from the wrist wound to a distance of a meter or two. This bleeding was checked by pressure and a dressing snugly applied. They were next dressed three days afterward, November 17th, at 2 P.M. The edges of the anterior wound were softened and necrotic. The posterior wound was apparently healed, except for some necrotic or purulent discharge at one end, and the stitches were removed from it. A rather loose dressing was applied. Pain and inability to sleep had continued, and the patient was pale, weak, and exhausted. Three hours after this dressing was put on the patient returned with the dressings completely saturated and dripping with blood, profuse hemorrhage having occurred; a new dressing was tightly applied.

During the following night and forenoon extremely profuse hemorrhage occurred repeatedly, saturating the dressings, bedding, and clothing with blood, and the patient was nearly exsanguinated. At 2 P M. November 18th, seven days after the original injury, I examined the wounds and found both widely gaping and filled with blood-clot and broken down tissue; blood was persistently oozing from the wound at the wrist, and the entire forearm was cold, blue, clammy, and much swollen. Although fairly certain that the case was one of hemophilia, I made a thorough search for bleeding vessels in the wound at the wrist, under chloroform, in order to be assured that the trouble was not due to primary or secondary hemorrhage. Incisions radiating from the edges of the wound were made and flaps turned up to expose it to its depths. The tissues were completely saturated and infiltrated with clotted blood, and the different kinds of tissue, ligaments, tendons, muscles, etc., all looked alike and were quite indistinguishable from one another; they were soft and friable, and tore easily in the forceps. No bleeding vessels were found, though several catgut ligatures were inserted deeply and tied. The bleeding seemed to consist of a general oozing, and was not checked even by the tourniquet. In view of recent results reported from the use of gelatin in hemophilia, a bacteriological culture-tube of sterile ten per cent. gelatin was melted and poured into the wound, after suturing the new incisions, iodoform gauze was packed in, and the wound dressed. Ergot was also ordered, a teaspoonful of the fluid extract, three times a day.

Little hope for the patient's recovery was entertained, and further hemorrhage would undoubtedly have proved fatal. From this time, however, an unexpected and most happy change in the course of the case took place. No more bleeding occurred, the pain disappeared, the patient became comfortable and was able to sleep. The wound was dressed November 20th, two days after the application, and was found in a highly favorable condition. The swelling and cyanosis of the forearm had entirely subsided, it was warm and rosy and its circulation good. The ecchymotic and broken down tissue in the wrist had undergone liquefaction necrosis and been absorbed into the dressings, leaving a nicely granulating ulcerated surface four or five centimeters in diameter. It was again dressed with gelatin, as before, and the ergot continued two days longer.

Henceforth the case followed the course of a healthy granulating ulcer, uninfected, and was treated in the ordinary manner. Early movement of the fingers was insisted on, and in five weeks the ulcers entirely healed, with motion and sensation of the fingers practically unimpaired.

In this case a hemorrhage which had been violent and uncontrollable for a week ceased immediately and in the most marked manner upon the application of gelatin, the administration of ergot, and the performance of an operation which apparently accomplished nothing. The result is probably to be attributed to the gelatin. The rapid improvement in the condition of the wound is also perhaps in part attributable to the local nutritive action of the gelatin.

In conclusion, it is perhaps too early as yet to fix a final estimate of the value of the hemostatic use of gelatin, but if such successful and remarkable results can be constantly obtained as have been claimed by some observers, it is certain that the agent would be of great value in the treatment of some very serious and intractable conditions. No claim has been made that gelatin is a specific in any class of cases, nor that it should supersede ordinary methods of hemostasis. In cases which resist other methods of treatment, and such cases are usually very serious and even desperate, gelatin offers some hope, if only a forlorn hope, of success. If only a portion of cases of hemophilia, which is such an appalling and disastrous complication, or of inoperable aneurisms, the treatment of which heretolore has at best been uncertain, yield to this agent, any proportion of lives thus saved, however small, will be ample justification for the use of gelatin.

*MICROBES AND COLD.**

BY FELIX VITALE, M.D.,
OF COYTESVILLE, N. J.,
FORMERLY LIEUTENANT-SURGEON IN THE ITALIAN ARMY AND FORENSIC PHYSICIAN TO THE CITY OF MONTEVIDEO, URUGUAY.

THE question of the resistance of microbes to cold has been discussed by most writers on bacteriology. It is to an American scientist that we owe the best work on this subject. Professor Prudden[1] deduced from his investigations of the growth of microbes in vessels surrounded by snow certain scientific principles which have not lost their value, and which may serve as criteria that will enable us to judge of the vitality and development of microbes at low temperatures.

In order to arrive at rational and exact conclusions, it is necessary to conduct our experiments as far as possible in such a way as to imitate the conditions found in Nature. Unfortunately Nature very jealously guards the secret of the methods by which microbes live and develop and succeed in invading organisms of a higher type; and it is impossible to reproduce in the laboratory the conditions presented in the production of disease. It is, for example, absolutely impossible to reproduce experimentally all the biological vicissitudes to which pathogenic microbes are exposed in sea-water or in potable water. The chemical constitution, the presence of organic substances suspended in the water, its movement, the variations of temperature, and the influence of light and air, the effect of the coexistent aquatic flora, the quantity, the age, the source, and the vitality of the species of microbes which occur in the water, are all conditions impossible to reproduce. It is nevertheless certain that every one of these conditions has its special influence on the micro-organisms contained in the water.

Prudden and Fraenkel[2] found in falling snow thousands of bacteria. Odo Buiwid demonstrated in hailstones a very large number of micro-organisms identical with those isolated from the soil of the locality in which the hail fell. On the other hand, Dr. Lewin of Stockholm in a recently published monograph detailing a series of investigations made during an island tour near Spitzbergen, announces that he found very few bacteria, not only in the snow of that region, but also in the intestines of a number of animals which he killed and examined on the spot. The intestine of a white bear proved, even after careful examination, to be completely sterile as far as bacteria were concerned. These results agree perfectly with the excellent hygienic conditions which prevail in these islands, for in them the ordinary maladies of the temperate region are almost unknown. The variations of temperature at that high degree of latitude are very sudden, and it is a well established fact that coryza, bronchitis, pneumonia, and the ordinary infectious intestinal diseases are quite unknown.

When we consider that Prudden found that the typhoid bacillus survived an exposure on the snow of 113 days, we can only arrive at the conclusion that while it may be true that cold can delay the development of microbes, permanently acting low temperature is necessary to deprive them of life. The factor which most of all brings about this destruction of microbes in very cold climates is the fact that the nutritive media

*Translated.

from which they normally derive their sustenance are so modified by extremely low temperatures as to no longer furnish them with the means of existence. The prolonged continuance of this state of affairs brings about the death of the bacteria. They may remain dormant for long periods, however, before death finally takes place.

The conclusions that may be drawn from these facts are applicable in epidemiology. In countries where the cold is intense and continuous for lengthy periods it influences not only the vitality of the microbe itself, but also all the substances that might supply it with nourishment. Hence it is very difficult to have a repetition of an epidemic in a cold climate even during the warmer weather which follows the intense cold. The exceptions to this rule demonstrate only the possibility of the continuance of microbic life despite the prevalence of low temperature. This possibility can be demonstrated as an absolute fact when microbes are transferred from the natural media on which they grow to artificial media.

Microbes require practically the same elements for life as plants of a higher order demand. Not only must conditions of temperature be favorable, but the soil to which the plant is transferred must be good, the transplantation must be carefully done, and a sufficient quantity of suitable nourishment must exist in the new soil. These last conditions are more important, as far as life is concerned, than temperature.

I do not wish, however, to be set down as expressing the opinion that the results which may be deduced from the study of epidemics are always constant. Hirsch seems to have established, and in this he is in agreement with practically all the observers on this subject, that the development of the germ of yellow fever occurs only between 22° C. and 25.5° C. (71° F.–76° F.), was not able to find any exception to this rule, except the epidemic at Georgetown in Guiana in the year 1852, the development of which coincided with a temperature of 19.8° C. (67.6° F.). In spite of this law that Hirsch considers to have practically no exception, the *Siglo de Montevideo*, a daily paper published in the capital of Uruguay, announced on the 8th of last June that cases of yellow fever were occurring at that time in Buenos Ayres in the Argentine Confederation. The wording of the announcement is of special interest. It says:

"With reference to the spread of cases of yellow fever in this city, while the temperature is little less than Siberian, it may be said that we have in this fact a phenomenon which completely refutes all the theories and opinions so far entertained with regard to yellow fever. Its occurrence during such cold weather has been the source of a great deal of surprise to scientific medical men." It will scarcely be necessary for me to add that Buenos Ayres is situated between the thirty-fifth and thirty-sixth degrees of south latitude, and that as a consequence the month of June there corresponds to our month of December. Likewise Dowler[5] makes the statement that in the epidemic of yellow fever in Northern Louisiana in the year 1853 he did not observe the slightest variation in the progress of the disease in a number of places despite the fact that frost was almost constantly occurring during the nights. Fenner of Mobile[6] relates that in the same year, though there was a severe frost on October 31st in New Orleans, he observed, nevertheless, a number of cases of yellow fever which occurred among people who had returned to the city from the camps after they thought all danger was over. In Memphis in 1878–79, in Cadiz in 1800 and 1801, in Malaga in 1808 and 1809, epidemics of yellow fever occurred two years in succession without having been imported.

But these, of course, are exceptions. The real question of interest for us consists in finding out whether microbes can exist at low temperatures. It is admitted by everyone that their reproduction and development are practically impossible during exposure to severe cold. Sternberg and Novy have made a deplorable error in this matter in not distinguishing between arrest of development and the death of microbes. When cold causes an epidemic to cease who can calculate how many days, or how many weeks, or how many hours even, the germ may continue to live? It would be absurd to claim that a microbe was dead simply because an epidemic had ceased. For instance, in the northwest of Hindostan and in the Punjab, cholera always ceases to be epidemic during the winter, yet frequently is aroused to epidemic activity the following spring. At Memphis the epidemic of yellow fever ceased completely during the winter of 1878, and yet broke out afresh in the spring of 1879.

But when we pass from the field of Nature to that of experiment the problem of microbic life is very much modified. We do not know the method by which Nature supplies micro-organisms with the organic substances necessary for their nutrition, nor how she supplies them with light and air. One thing is certain, our artificial media compel microbes to live a life quite different from that which they live in Nature. It is for that reason that all bacteriologists recognize as a law in biology the principle that may be stated about as follows: When micro-organisms pass from natural to artificial media they always undergo more or less important modifications. As an

example of this law may be cited the virulence which a microbe may acquire, though it did not possess it when first isolated. The typhoid bacillus furnishes a good instance of this. It does not possess great virulence when first isolated from the cadavers of those who have died from typhoid fever. When grown on artificial culture media it is but moderately pathogenic, but acquires distinct virulence later on. The bacillus of the plague, when first isolated from the cadaver and grown in bouillon cultures is virulent even when taken by way of the digestive tract. But after two or three passages through animals it loses some of its virulence, no longer produces the disease when taken by way of the digestive tract, and causes symptoms of the disease only when administered subcutaneously or intraperitoneally. It may be added, however, that microbes undergo modifications not only as to their pathogenic manifestations, but also with reference to the resistance which they ordinarily offer to various inhibitory influences, both physical and chemical.

Cultivation in the ordinary media makes great differences in the vital resistance of microbes. The biology of the gonococcus furnishes a very convincing proof of just this fact, since its failure to resist external agents, and especially low temperature, depends on the extreme difficulty of accustoming it to grow on artificial media. It will not be out of place since this microbe has been quoted as one of those that offer very little resistance to low temperatures to review a little of its life in the laboratory.

Wertheim employed a mixture of human serum with serous fluid, which remained liquid at 40° C. Christmas, after having tried all the albuminous liquids that could be obtained from human beings, the serous fluid of ascites, of pleurisy, and a number of other animal serums, found that the serum of the rabbit was the best nutritive medium on which to grow it. The microbe develops abundantly, but does not remain alive more than three or four weeks, though sometimes it has been kept alive for two months after inoculation. The best results have been obtained in liquid culture media employing ascitic fluid with three parts of peptone bouillon. Glucose may be a useful addition to the medium, but must not be added in more than a proportion of one per thousand. In this mixture the gonococcus develops, but the development does not begin until the second or third day at 38.5°C. (101.3°F.) and proceeds gradually until the seventh or eighth day at which time development is complete. If from this first liquid-culture, however, one wishes to make a second inoculation it does not succeed, that is to say, the microbe will not permit a passage from the first tube where it has developed to a second one.*

The transference of the gonococcus when taken from the urethra and inoculated on serum requires special precautions. The pus should be evenly spread on the surface of the coagulated fluid and not a moment must be lost in placing the tube immediately in the brood-chamber, otherwise the organism will not develop. Even under these circumstances it develops only between 32° C. and 38.5° C. (89.6°F.–101.3° F.). If the temperature is below 32° C.; or above 38.5° C. no development takes place. The inoculated gonococci die in a few hours at 15° C. (59° F.). That is to say at 59°F., not at 15°F., as Dr. Novy wrote erroneously.

This brief review of the bacteriology of the gonococcus shows that it is absurd to quote this microbe as an example of those which do not resist cold. Its extreme delicacy under ordinary circumstances, which permits it to live only for a few days even on its favorite culture media, human and rabbit serum, show that it is almost as absurd to talk of the vitality or resistance of the gonococcus as it would be to talk in the same manner of the spirillum of Obermeier, for which, as is well-known, we have as yet no successful culture medium. Besides it must be remembered how readily the pathological liquids on which the gonococcus is grown become modified by circumstances, for this tendency has an important influence on the vitality of the gonococcus.

Let us apply the biologic law mentioned above to the microbes of two diseases which are almost absolutely endemic in tropical regions, the vibrio of cholera and the bacillus icteroides. Let us suppose for the moment that neither cholera nor yellow fever has ever made its appearance during a cold season. When the bacillus icteroides and the vibrio of cholera are first isolated from the cadaver they do not easily adapt themselves to life in bouillon. It is only after a time that they acquire an adaptation to artificial culture media. The first inoculations in bouillon always give very sparse growths. Later, however, both bacilli adapt themselves to the artificial media; cultures in bouillon may be obtained regularly and considerable cloudiness showing abundant growth always results. Their conduct during this process of adaptation to artificial media shows that both microbes are possessed of considerable resistive vitality. It is true they may lose some of their virulence during the process, for it is to be remembered

* Dr. Heiman's researches in this country with reference to the gonococcus are a very interesting confirmation of the facts already known as to the extreme delicacy of the gonococcus when grown on artificial media. The detailed account of his work will be found in the *Medical Record* for June 22, 1895, December 19, 1896, *et. seq.*

that the virulence of a culture may be in inverse proportion to the activity displayed in development.

I brought with me from Montevideo some tubes containing cultures of the bacillus of Sanarelli. Of these, two proved to be sterile as far as further inoculation into bouillon or upon agar were concerned. Two of them, however, gave very abundant growths in bouillon, but the specific virulence of the microbes was practically nil. A rabbit inoculated with 1 c.c. of culture lost but 300 grams in weight in eight days and then began to recover. When the microbe was first isolated from the cadaver of a patient dead from yellow fever it was extremely virulent and it required but a very small quantity to kill a rabbit in from two to four days, for the rabbit is very sensitive to the bacillus icteroides as a rule. As a consequence it is possible that, despite the fact that neither cholera nor yellow fever may ever have made their appearance during the winter time, the germs of these diseases may adapt themselves to life on artificial media and possess under the new biologic conditions a resistive vitality that they do not possess when grown on natural media.

Besides this it is far from scientific to expose a microbe to cold when grown in a tube of bouillon or agar and then argue as to its vital power. Practically this would be same thing as to expose a tropical plant to cold under such artificial conditions that it is well protected from cold. An argument founded on such fallible experimental observations would have as little weight as the personal experiments performed by Dr. Chervin in 1816 at Pointe a-Petre in the Antilles. Dr. Chervin drank large quantities of the black vomit from yellow-fever patients and for some time wore their clothing; as he did not contract the disease he drew the conclusion that yellow fever was not contagious.

The serious scientific observations which have been made with reference to microbes and cold seem to have been completely lost upon those who would demonstrate that the bacillus icteroides is not the cause of yellow fever because it continues to live in spite of exposure to low temperatures. Too many insoluble problems are connected with this intricate question of the behavior of microbes to cold to allow it to be used as a simple criterion by which to judge of the pathogeneity or non-pathogeneity of a given micro-organism. Those who found their arguments upon this behavior to cold, seem to have lost sight of certain physical laws regarding the action of refrigeration on organic substances generally. Besides they do not seem to have recognized the fact that a symbiosis of microbes with certain parasites of a higher order may lead to a prolongation of life under unfavorable circumstances. They seem also to have confounded living with the power of propagation, etc.

In this matter a look at the exact period in which various epidemic affections begin to develop and are arrested in a certain focus of disease will prove very interesting. As a matter of fact epidemics of yellow fever begin in Rio Janeiro usually in the month of February; in Havana the month in which most cases of the disease have usually occurred has been September. In New Orleans and Charleston most cases occur from August to November. In other words, it is necessary that the warm weather should first, for a time, elaborate the nutritive materials which are necessary for the development and for an increase of virulence of the micro-organisms. It is only after this has occurred that the germ of yellow fever becomes sufficiently increased in virulence to invade the human organism. If temperature alone were the only factor on which its power to attack human beings depended, then, at Rio Janeiro the epidemics would begin as a rule in November or December. In Havana, June would be the worst month for the disease and it would be about the same time of the year that epidemics in New Orleans would be at their height.

From these facts I think we can deduce the conclusion that all microbes offer resistance to temperature that bears a certain relation to the medium in which they live and that this relation varies not only for low temperatures, but also for temperatures above the normal. Chamberland demonstrated in a two-branched Pasteur tube that the spores of bacteria exposed to boiling temperature offered a resistance to heat which varied according to the nutrient medium in which they were placed. In liquid yeast, for instance, spores of bacteria remained alive for five hours after boiling. In a hay infusion they also remained alive for five hours, in a Liebig bouillon solution they remained alive but for three hours, in must of grape that had been carefully neutralized they were killed by boiling in half an hour. In a nutritive solution whose acidity was more than two per thousand bacteria remained alive at a boiling temperature for only ten minutes.

In conclusion then we may say that the temperature exerts an influence on microbes which bears a direct relation to the media in which they are being cultivated, and the resistance they offer is just so much greater as the media on which they live, whether they be natural or artificial, are favorable to the vitality of the microbes.

EXAMINATION OF THE BLOOD IN SURGICAL DISEASES.[1]

BY H. STUART MACLEAN, M. D.,
OF RICHMOND, VA.,
LECTURER ON BACTERIOLOGY AND PHYSICAL DIAGNOSIS AND DIRECTOR OF THE MICROSCOPICAL LABORATORIES AT THE UNIVERSITY COLLEGE OF MEDICINE; BACTERIOLOGIST AND HEMATOLOGIST TO ST. LUKE'S HOSPITAL.

ALTHOUGH this branch of physical diagnosis has been known but a few years it has advanced with such rapidity that it has now reached the position of an important, often indispensable, method. Not only in surgical diseases, of which this paper is a partial review, but in medical practice also is found a field even wider and of greater practical application, concerning which another paper is to be read at a subsequent meeting. The enumeration of the red corpuscles can be but briefly mentioned, as the subject could well occupy the entire paper, and I will but call attention to the variation in their number occurring after hemorrhage. Immediately following the loss of considerable blood little change in the blood elements will be noticed as the loss has been general and the proportions remain the same. Within an hour, however, fluid begins to enter the vessels from the tissues, greatly diluting the serum but producing more volume for the heart to contract upon and thus raising the blood pressure. This dilution of the serum of course produces a corresponding diminution in the number of red corpuscles (the white, as we shall see later, are not decreased). A count, therefore, in a case of hemorrhage will show a decrease in the number of red cells to even as low as one or two million per c.mm., whereas the normal is about five million. It is readily seen how valuable such evidence may be in the diagnosis of a hemorrhage into closed cavities.

In connection with the same emergency (hemorrhage) the value of estimating the hemoglobin present may be considered as this substance diminishes proportionally with the diminution in number of the red cells. Attention might be then called to the attitude of the well known surgeon Mikulicz, who is so fully convinced of the value of blood analysis that he has formulated the rule: never operate on any case when the hemoglobin is below thirty per cent. This is applicable to all cases where this reduction in hemoglobin is found and not to those of hemorrhage only.

The white corpuscle or leucocyte is at present receiving a very great amount of attention from pathologists. Its prominent local activity in all inflammatory conditions has been thoroughly recognized, since the researches of Metschnikoff, Buchner, Massart and others, but concerning its actual utility either in an area of inflammation, or in the circulation in certain inflammatory disturbances, there is still some dispute. It seems more than likely, however, that it is the function of the leucocytes to produce some material concerned in counteracting the toxins produced during the disease. The orginal theory of Metschnikoff that "inflammation is a combat waged by the cells against intruders or disease producers," has undergone some modification; as Ziegler says "such a manner of characterizing the phenomena of phagocytosis amounts simply to a poetical way of expressing one's self and does not do justice to the essential facts." However, no matter what the functions of the colorless corpuscles may be, it is certain that in various diseases their enumeration affords opportunity for both differential diagnosis and prognosis. The leucocytes are normally present in the peripheral circulation in the proportion of from six to nine thousand per cubic millimeter, and any temporary secondary increase is spoken of as a leucocytosis. In all cases of inflammatory disturbance accompanied by pus formation leucocytosis is an invariable accompaniment (except in a few instances to be mentioned further). The suppurative process may be acute or chronic, deep-seated or superficial, encapsulated or diffuse, but the leucocytosis is present. Before detailing some of the conditions where the application of this fact is of practical importance some general laws should be cited. (1) The leucocytosis is not confined to the area involved in the inflammatory action. It is found throughout the peripheral circulation. (2) Pathologic leucocytosis must be differentiated from the normal digestive leucocytosis, which commences about one hour after eating and continues for two to four hours, depending upon the rapidity with which digestion takes place. It is therefore best when examining the blood to count the leucocytes just before or just after a meal. The preferable time is just before breakfast. (3) Leucocytosis occurs in the majority of cases of pregnancy during the last five months. (4) As a rule pathologic leucocytosis is in excess of what a physiologic leucocytosis would be, in the latter the white cells rarely exceeding twelve or fourteen thousand to the cubic milli-

[1] Read at the Annual Meeting of the Medical Society of Virginia, held at Richmond, October 24, 26, 1899.

meter. The reliable method of differentiating in doubtful cases lies in choosing the proper time for the examination.

Among the more prevalent and important diseases in which leucocytosis is found the following may be mentioned.

Abscess.—Whether the accumulation of pus be of recent origin and accompanied by acute inflammatory disturbances or is chronic ("cold"), the increase in the number of leucocytes still holds good. The presence of pus is revealed by the blood-count, and neither the thickness of the abscess wall nor the pressure under which the pus is elaborated seem to influence the number of leucocytes. The presence of leucocytosis begins with the formation of pus and increases with it. Leucocytosis is not always proportionate to the amount of pus present; the writer has counted the leucocytes in a case of a small abscess on the back of the hand and found 27,000 to the cubic millimeter, while in a case of purulent appendicitis there were 17,000 to the cubic millimeter. This may appear at first glance to detract from the value of the count, but such is not the case. In both cases the blood examination proved the existence of pus, and taking each case separately we would find a leucocytosis varying as the amount of pus increased and diminished. As a matter of fact, the amount of leucocytosis is due, not so much to the mere presence of pus as to the resisting power of the patient.

Abscess of the liver may be affirmed or excluded by counting the leucocytes. The deep-seated nature of this trouble often is a serious obstacle to a correct diagnosis by physical examination and many diseases may simulate it, such as malaria, duodenal catarrh and impacted gall-stones. In case No. 10 the diagnosis was confirmed by blood count, while on another occasion (case No. 11) a negative diagnosis was also confirmed by further examination. Not infrequently in laparotomies performed for the removal of suppuration foci a temperature will develop on the second to the fifth day which may be due to reinfection, impaction of feces, or malaria. The existence of a pocket of pus (case No. 22) is readily determined by counting the leucocytes.

Appendicitis.—In this disease more than in any other has the value of a leucocyte count been demonstrated, and the majority of surgeons regularly make blood counts in suspected cases. The leucocytosis of appendicitis varies, in a measure, according to the form and amount of inflammation. In simple catarrhal appendicitis the leucocytosis may be absent or very slight, depending on the amount of inflammatory reaction which has occurred in and about the wall of the appendix, while in purulent and gangrenous appendicitis the number of leucocytes is always increased, often to a marked degree. The fact that leucocytosis is not constant in catarrhal appendicitis is by no means an objection to the method, as surgical intervention is not indicated in this form during the attack (case No. 6). As the disease progresses, however, with resulting pus formation or gangrene, leucocytosis appears and is a reliable index to the advance of the disease and the necessity for immediate surgical intervention. Hence it will be seen that this point may be of very great value in diagnosis, differential diagnosis and prognosis It detects the advance of a case from the simple catarrhal form to the purulent or gangrenous, *i. e.*, from the non-operative to the operative; and in the latter form it shows the true progress of the disease irrespective of prominent symptoms, which are too often misleading (case No. 4). The greatest practical applicability of this method will be found in the differential diagnosis of appendicitis.

Diseases which often simulate appendicitis, such as hepatic or renal colic, intestinal colic, intestinal obstruction (without gangrene), fecal impaction, typhoid fever, nephralgia, floating kidney, ovaralgia, old adhesions (quiescent), and tubercular peritonitis, are all readily differentiated by their failure to cause leucocytosis. Three times has the writer decided against appendicitis in cases which subsequently proved to be typhoid fever (cases No. 1, 2, 3), and on one occasion a diagnosis of impacted gall stones was suggested in a case where appendicitis was suspected (case No. 7).

Pyosalpinx.—This disease is frequently met with and has to be differentiated from, a prolapsed and inflamed ovary, ovarian neuralgia, ectopic gestation, small extraperitoneal hematoma or inflamed fibroid. The diagnosis is usually easy (cases Nos. 19-20), as any pelvic lesion attended with leucocytosis is almost certainly a pus tube or other localized collection of pus.

Osteomyelitis.—Patients with suppurative disease of the medulla of the bone who have been treated for considerable periods of time for "rheumatism," neuralgia, or even thought to have typhoid or malaria have been met with by most physicians, and often the diagnosis has been made only when pus has risen to the surface and "pointed;" a time when surgical intervention is practically powerless to effect any relief. Indeed such cases are not always readily diagnosed even by expert clinicians. The persistence of the disease, however, should arouse suspicion, and in cases of osteomyelitis a blood examination will always reveal a marked leucocytosis unless the osteomyelitis be tubercular (case No. 18).

Tuberculosis.—This disease appears to the surgeon in many disguises and the question of the tubercular or non-tubercular character of a case often assumes a serious aspect. Fortunately, in pure tubercular lesions, whether accompanied by pus formation or not, there is no leucocytosis; indeed there is little change in the blood Should a tubercular knee-joint, for instance, become infected with pyogenic micro organisms, the leucocyte count at once rises. In a case of cervical glandular enlargement with fluctuation, absence of leucocytosis established a diagnosis of tubercular abscess which was confirmed by subsequent examination of the pus (case No. 17).

Shock.—The question is often an anxious one to the physician and surgeon whether a given case of shock is due to concussion or compression or to hemorrhage. If the case be one of shock of nervous origin, the blood will show no change, while in the shock of hemorrhage we find the red corpuscles reduced, as already mentioned, and the leucocytes increased. This leucocytosis commences within an hour or so after hemorrhage has occurred and persists for days, sometimes weeks. The value of this fact can hardly be overestimated when we consider how frequently the question of the advisability of employing transfusion arises. The old method of judging the appearance of the patient has proved itself sufficiently unreliable, in addition to its being unscientific. Cabot[1] says "The right decision of this question is of great importance, for if the 'shock' means anemia, transfusion may be indicated, while, in a condition of cerebral concussion or compression transfusion will probably do harm."

These are but a few of the diseases in which a blood-count is often applicable and I doubt not that the value of this method is recognized by all. From fifteen to thirty minutes of bed side work may be done, and the result is, that many an obscure case is cleared up, or a prognosis can be made which will relieve the strain of both physician and friends. The following are some cases selected from the writer's work during the past year or so, bearing more or less directly on the diseases mentioned in the body of the paper:

Case I.—Male, adult, indefinite abdominal symptoms referable to either typhoid or appendicitis; leucocytes, 7300; case ran a typical typhoid course.

Case II.—Male, child, case thought to be appendicitis, operation advised by consultant; leucocytes, 6800; diagnosis of typhoid confirmed by Widal's test.

Case III.—Female, seventeen years; sick one week; all symptoms referable to right side; leucocytes, 6100; diagnosis, typhoid fever.

Case IV.—Male, adult; appendicitis; symptoms of abscess; leucocytes, 19,600. Twenty four hours later temperature, pulse, and general condition better; leucocytes, 22,000; next day symptoms still improving; leucocytes, 27,000. Operation urged, as abscess was believed to be increasing in size; on operating found necrotic appendix, in abscess cavity containing nine ounces of pus.

Case V. — Male, thirteen years; leucocytes, 31,200. Gangrenous appendix found.

Case VI.—Male, adult; appendicitis diagnosed. Question of advisability of operating, as symptoms of pus formation, high temperature, chills, etc., were present. Leucocytes, 9600. Catarrhal appendicitis diagnosed. Ten days later operation showed appendix surrounded and bound down by many adhesions; no pus.

Case VII.—Female, adult. Appendicitis suspected. Leucocytes, 7400. Further search showed impacted gall-stones.

Case VIII.—Male, twenty-nine years. Appendicitis diagnosed in preceding attacks; present attack a mass is felt in right lumbar region. Leucocytes, 7000. No diagnosis made other than that surgical intervention was necessary. Operation showed obstruction due to old adhesions; appendix normal.

Case IX. — Female, adult; symptoms of obstruction of gall-bladder. Leucocytes, 14,000. Operation showed empyema with impacted gall-stones.

Case X.—Male, adult; symptoms of fever, chills, sweats, and nausea. Leucocytes, 17,200. Diagnosis, hepatic abscess. Operation showed large abscess of right lobe.

Case XI.—Male, adult; supposed case of hepatic abscess. Leucocytes, 6800, excluding pus. Subsequent examinations revealed abdominal aneurism.

Case XII.—Female, adult; leucocyte count of 31,000 established the diagnosis of mammary abscess.

Case XIII.—Female, adult. The clinical symptoms of appendicitis with abscess formation were corroborated by a leucocyte count of 16,000.

Case XIV.—Female, child. Case was being treated for malaria, and while examining for plasmodium a leucocytosis of 24,000 was found. Further search revealed purulent appendicitis.

Case XV.—Male, child. Case of peritonitis, tuberculosis suspected. Leucocytes, 19,300. Tuberculosis thereby excluded.

Case XVI.—Male, adult. Leucocytes, 28,700. Pus somewhere was diagnosed three days before a perinephritic abscess was discovered.

Case XVII.—Female, child. Enlarged cervical gland with fluctuation. Leucocytes, 6200. Diagnosis, tubercular abscess.

Case XVIII. — Male, adult. Case was being treated for muscular rheumatism, and blood examination was asked for to detect indications of malaria. The leucocytes were found to be 20,600, and the suspicion of osteomyelitis was afterward confirmed by operation.

Case XIX.—Female, adult. Pus tube suspected

[1] "Inter. Text-Book of Surgery," vol. i., p. 81.

from examination of tumor. Leucocytes, 8000. Diagnosis, inflamed ovary, confirmed by progress of case. Patient made rapid recovery under appropriate treatment.

CASE XX.—Female, adult. Pus tube suspected. Leucocytes being only 7900, pus was excluded. Case proved to be prolapsed and painful ovary.

CASE XXI.—Male, adult. Thrown from horse, badly bruised. Leucocytes being 9100, red cells 4,700,000; a diagnosis of concussion was made, which proved correct.

CASE XXII. — Female, adult. Laparotomy for pus tube. On fourth day temperature was 101° F., and patient had a slight chill; wound healthy. Leucocytes, 23,700. Pocket of pus diagnosed and confirmed by vaginal examination. Vaginal drainage released an ounce of pus and relieved all symptoms.

CLINICAL MEMORANDUM.

LOSS OF INTESTINE AND ITS EFFECT ON THE NUTRITION.

BY JACOB R. JOHNS, M.D.,
OF PHILADELPHIA.

NEARLY five years ago I reported[1] a successful case of intestinal anastomosis after the loss of two and one-half feet of intestines. A few years ago it was held that the loss of more than a few inches or a foot of intestine would certainly prove detrimental to adequate body nutrition, but the following list adapted from a paper on the subject by Professor Francis J. Shepherd[2] shows the possibilities of recovery:

	Operator.	Total Loss	Nature of Lesion.	Time After Which Health was Still Fair.
1	Ruggi	130 inches	Multiple Stricture	Two years
2	Shepherd	92 "	Tumor of Mesentery	Seven Months
3	Kocher	82 "	Railway Injury	Six Months
4	Koeberle	73¼ "	Multiple Stricture	" "
5	Kocher	63 "	Strangulated Hernia	" "
6	Schlange	53 "	" "	Two years
7	Eliot	48¾ "	Gangrene of Intestine	" "
8	Roux	48¾ "	Tumor of Mesentery	Six Months
9	Trombetta	43½ "	(Not stated)	" "
10	Werder	42 "	Tumor of Mesentery	" "
11	Hahn	31½ "	(Not stated)	" "
12	Beaver	30 "	Strangulated Hernia	Five years

Grybicky, who experimented largely upon lower animals, concludes, after much careful study, that in an emergency a healthy adult can afford with impunity to surrender as much as nine and one-half feet of intestines; but all the authentic cases of considerable loss of intestine thus far reported neither prove nor disprove the correctness of his statement. Ruggi's extraordinary case occurred in a boy, and the total loss stated represents the excision of the intestine at two different operations, separated by a considerable interval of time. In another case, No. 3 in the list, there was a marked tendency to diarrhea, and in a few others the history shows that careful dieting was necessary to avoid this condition. True, the majority of patients on the list gained flesh and showed no serious disturbance of digestion or assimilation, but this condition of physical well-being seems due rather to the mild character of the lesion which necessitated the operation rather than to any other feature of the case. Other conditions being equal those patients having a traumatic lesion can bear a greater loss of intestine than those having a pathologic lesion. This may be seen in comparing the conditions found in multiple stricture, gangrene or tumor of the mesentery with those of simple strangulation.

The case which I reported, with an operation by Doctor Beaver, was uncomplicated from first to last, and now after the lapse of five years the patient continues in excellent health, and is even better than before his loss of thirty inches of intestine. I quote the closing paragraph of the first report: "The gain in flesh after the resection and before the patient left the house was considerable. In the fifth week, when he was weighed, twenty-two pounds of his original weight were still lacking. The first week after weighing he gained six pounds; the second week, four pounds; the third week, three pounds; the fourth week, two pounds; and in the thirteenth week after the operation, which was to establish a fecal fistula and the eighth week after resection, he reached his former weight and felt as well as ever."

The resection was effected by the aid of a Murphy button which was voided quite unbeknown to the patient on the seventeenth day. Twelve hours after the operation for resection he had the first fecal movement, his first rectal discharge in five weeks. After the eighth day he had daily movements: at first there were four or five stools each day but later they became fewer. The manner in which the normal intestinal functions returned, as judged by the stools, was interesting. After a few weeks the number of daily stools was reduced to three; two occurring in the early morning and one at night. The stools were then thin and unformed. A few weeks later he had but two daily movements, night and morning, and the stools began to be partly formed. Later still there was no night movement and formed stools became the rule. Up to the present time he has had one normal stool daily with a clock-work regularity. After sufficient time had passed to complete cicatrization all restrictions of diet were removed and he has since eaten and worked as usual. His body weight has fluctuated between 150, his weight before operation, and 164, according to the season. He no longer has a hernia and is in every particular in perfect health.

MEDICAL PROGRESS.

Ludwig's Angina.—HAMANN (*Cleveland Jour. of Med.* September, 1899) thinks it better to drop the term "Ludwig's angina" as it is applied to a number of different inflammatory conditions in the neck whose etiology and course are now well understood. They are produced most commonly by infection through the lymphatics from some lesion of the mouth or pharynx. Laryngitis results

and then lymphadenitis, and to the latter is often added perilymphadenitis with cellulitis. A much rarer mode of infection is through the ducts of the salivary glands, particulary the submaxillary. In cases of gangrenous diphtheria cervical abscesses may form containing a thin putrid pus. The description of the cervical fascia has been made unnecessarily complex. What one needs to know is that there are certain spaces between the various organs of the neck filled with a loose connective tissue that allows the mobility of the parts. Into these areas inflammatory processes extend and in them pus forms. If the lymphatic glands contained within the capsule of the sub-maxillary gland suppurate, there will result marked tension of the capsule with more or less surrounding edema. Another space for infection lies between the trachea, larynx, and thyroid, and the muscles in front of them. Abscesses situated here may press upon the air passages and extend into the anterior mediastinum. A third space is around the great blood vessels of the neck. Abscesses here will raise the sternomastoid muscle and may point between this muscle and the trachea or may extend into the mediastinum. A fourth space is behind the esophagus and pharnyx and is known as the retro-visceral space. Post-pharyngeal abscesses occur in this situation. A fifth space is at the lower end of the sternomastoid, bounded posteriorly by the great vessels and the scaleni muscles. This space is in communication with that of the carotid and jugular vein and also with the axilla. These spaces are not entirely separated from one another but an inflammatory process beginning in one of them does not extend to others until tension is considerable. The extent of edema and induration may make it impossible to say, however, in what space the trouble began if the patient is first seen some time after its commencement. Sometimes there is a board like induration of the whole side of the neck. This may remain for days or weeks and then subside without the formation of pus or with the formation of one or many small abscesses. The author recommends the application of hot poultices and a small incision as soon as the presence of a soft spot indicates the existence of pus. Closed artery clamps are then introduced into the abscess and the wound stretched by separating their blades. Gauze drains or drainage-tubes, if the pus is thick, and wet dressing complete the treatment.

The Rubber Finger-Cot in Obstetrics.—BOND (*Maryland Med Jour.*, October 14, 1899) recommends the rubber-finger cot for vaginal examinations, especially in obstetric cases. It protects the finger from poison, it glides easily into the vagina, and does not bring away the lubricating mucus to the extent that the bare finger does. The vulva should be washed, the labia separated, and covered with a fold of fresh gauze or a piece of fresh muslin containing a vertical slit. The finger may then be introduced without coming in contact with any unsterilized surface. By these simple measures asepsis is secured and the physician is saved the time and trouble of attempts at disinfecting the hand by means which often appear to the patient to be needlessly complicated. The finger-cot can be laid aside in a disinfecting solution until the next examination, but each time a fresh piece of gauze should be used. All necessary information can be gained through this thin rubber. For rectal examinations or the digital examination of any unwholesome cavity, the rubber-cot ought to appeal to every surgeon who cares for cleanly hands.

Fatal Umbilical Hemorrhage.—COFFART (*Jour. des Sciences Médicales*, August 26, 1899) reports a case of fatal umbilical hemorrhage occurring in a child ten days old. The physician in charge of the case ligated the cord as usual and wrapped it in linen soaked with oil. It came away spontaneously on the sixth day. On the ninth day the skin showed evidence of jaundice. The following night when lifting her baby to the breast the mother discovered that its clothing was soaked with blood. The umbilicus was still bleeding and the hemorrhage could not be stopped. The physician was sent for and found the blood slowly oozing from the umbilical stump. Digital compression, cauterization with nitrate of silver and dusting with antipyrin failed to stop the hemorrhage. It ceased, however, after the application of cotton soaked in a ten per cent. solution of antipyrin. Two hours later it recurred and in spite of attempts to stop it the child died at midday. The author attempts to trace the relation between icterus and the fatal hemorrhage. In his opinion, the icterus was of an infectious character and the unprotected stump of the cord was presumably the point of entrance. The impoverishment of the blood and the diminution of the globules produced by the icterus predisposed to the fatal hemorrhage.

Abscess of the Brain.—SIMS (*Va. Med. Semi-Monthly*, September 8, 1899) mentions a case of brain abscess occurring under peculiar circumstances. A captain in the United States Army suffered with symptoms of nervous prostration which became so bad that he was given a year's leave of absence. At the end of that time he returned to duty much improved in health, but still excitable, easily fatigued, complaining of indigestion, constipation, and myalgic pains. After a long trip in a rough vehicle, he suffered for several days with headache followed by neuralgic pains in the left side of the head. Various remedies failed to relieve this but it was temporarily helped by hypodermic injection of morphin. The symptoms grew worse so that in ten days vision was partially lost and delirium set in, and on the fifteenth day the patient died. The autopsy revealed the presence in the left frontal lobe of an old abscess the size of a hen's egg, with thickened walls and inspissated pus. It was entirely in the central portion of the brain, not affecting the cortex at any point. There was a recent rupture of the abscess downward and backward through the basal ganglian and into the medulla. Apparently the original abscess had existed for two years, becoming encapsulated after the prolonged rest in hospitals.

Monobromid of Camphor in the Treatment of Epilepsy.—HASLE (*La. Gaz. Hebdom.*, September 3, 1899) recom-

mends strongly the use of the monobromid of camphor in the treatment of epilepsy. On account of its odor and taste it may be given in pills or hypodermatically. The following solution may be used for that purpose:

℞ Camphor monobromid . . gr. xxx
Alcohol . . . . 3 iv *m.* x
Glycerin . . . . 3 iii *m.* x.

As a large number of injections will be necessary if this solution is used, it is perhaps best to give the drug in capsules. The dose may be increased, if necessary, up to a dram. It has been found useful in hysterical forms of insanity and in different forms of hysteria as well as in epilepsy. It will prevent nightmare. If persisted in it will cause attacks of epilepsy to disappear, but its use should be continued several days after the disappearance of the symptoms.

THERAPEUTIC NOTES.

Belladonna in the Bronchopneumonias of Children.—HODGHEAD (*Pediatrics*, September 1, 1899) cites some striking instances in which bronchopneumonia in a child was quickly overcome by the administration of drop doses of the tincture of belladonna given every hour. Encouraged by the success which followed this treatment in the first case, the writer adopted it in twenty-five others in his own practice and it was also carried out in five cases in the practice of other physicians. The belladonna was in every instance preceded by small doses of calomel until the bowels moved freely. Twenty-eight of the thirty patients thus treated recovered. The action of the belladonna in small doses is a mildly narcotic one that increases the comfort of the child. It raises the arterial tension and stimulates the cardiac sympathetic, thus acting as a heart tonic. It is also a respiratory stimulant. It dilates the superficial capillaries and relieves the congested lungs; but by far its most important influence is to diminish the secretion of the bronchial tubes and thus to evert the threatened asphyxia. To attain the required effect it has to be administered in quite large doses every hour or two. Children are not very susceptible to the drug and infants a few months old may take with safety as much as a child of six. By administering the drug in frequent doses it can be withdrawn if any unpleasant symptoms arise, although in no one of the thirty patients treated did any dangerous complication appear.

Treatment of Chronic Gastric Catarrh.—EINHORN ("Twentieth Century Practice," vol. viii) says that, in the first place, the diet should be regulated in accordance with the severity of the symptoms. Four meals a day, for the most part of liquid or semisolid food, should be taken. After a week or two of this regimen the diet should be changed, and made to correspond as nearly as possible to that ordinarily taken. Vegetables should be eaten in large quantities, but meats should be somewhat limited. Meat that is very fresh, or that of tough fiber, such as pork, and such articles as sausages, lobster, salmon, chicken salad, mayonnaise, cucumbers, pickles, cabbage, and strong alcoholic drinks should be strictly avoided. The patient should eat slowly, masticate well, should not think of business during meals, and should stop eating before a sensation of satiety appears. He should lead a rational hygienic life, his hours of business should not be too long, and he should take plenty of exercise, though avoiding overexertion. Upon rising in the morning he should take a cold sponge-bath, and follow it with a brisk rubbing with a coarse towel.

Lavage may be necessary, especially in the mucous form of the disease. This should be carried out every other morning for two or three weeks, the patient being in a fasting condition. Lukewarm water with the addition of a little common salt should be used. Electricity and the use of mineral waters may be necessary to bring about a cure. Drugs are not relied upon to nearly as great an extent now as formerly. If the gastric juice is deficient in hydrochloric acid 6 to 12 drops of the dilute acid in half a pint of water should be taken in three parts at fifteen-minute or half-hour intervals three times a day after meals. Pepsin is absolutely inefficient. Artificial aids to digestion are not necessary, and if given are frequently injurious. Fluid extract of quassia, columbo, or condurango, 20 drops, or tincture of nux vomica, 10 drops, in half a wineglassful of water may be given before meals with advantage in many cases.

The Treatment of Epistaxis.—RAUGE (*Rev. de Therap.*, July 15, 1899) says that every epistaxis is a surgical hemorrhage demanding surgical treatment. The first indication is to look for its source. The ala of that side of the nose from which the blood comes should be lifted sharply upward, while the septum is bent in an opposite direction. This maneuver often suffices to disclose the bleeding-point, which is usually situated about an inch from the tip of the nose. A speculum is not needed, and is often in the way. Sometimes the exact bleeding-point cannot be seen, but pressure upon the area from which the blood comes, made with the finger or with a clamp covered with a little gauze, will stop the hemorrhage Should the blood come from a deeper portion of the nose it is necessary to apply tampons. They should be introduced through a nasal speculum. Small bits of absorbent cotton are packed in one after another. It is important that they should be very small. The cotton may either be used plain or saturated with some astringent or with peroxid of hydrogen. Before resorting to tampons it is well to try the effect of a very warm injection, 40° to 45° C. (104° to 113° F.°). In a few cases it may be necessary to pack the posterior nares. Tampons should not be left in more than twenty-four hours. At the end of this time they should be removed, and the nasal cavity disinfected. If necessary, tampons may be reintroduced.

For Punctate Acne.—

THE PRESENT STATUS OF HYDROTHERAPY.

Some recent contributions to hydrotherapy by physicians of merited eminence direct attention to the ancient therapeutic method, which appears to have taken a new lease of life, if we may judge from its warm espousal by men who are not specialists in that branch of therapeutics. In the *American Journal of Insanity* (No. 4, 1899) Dr. Foster, physician to the Goverment Hospital for the Insane, writes: "Hydrotherapy to-day rests upon the same basis of physiologic investigation and clinical study as is involved in determining the scientific application of any therapeutic agency. Those who lead the thought and practice of the profession are practically unanimous in this favorable attitude towards it."

In a recent essay on hydrotherapy Professor Putman of Harvard University discusses its "scientific basis," and says that he "can corroborate from his own experience the favorable statements made by others regarding its results in chronic affections characterized by debility, anemia, and in the neurasthenic states." In the discussion of this essay Dr. Rogers said that, having used water in the treatment of disease for twenty-five years, he ranked it with opium, cinchona, iron, and alcohol; he felt sure that by the aid of hydrotherapy he had seen cures or improvements in cases not successfully treated by others or by himself with drugs and hygienic measures. It is almost time that the Medical profession awoke to the fact that hydrotherapy has at last established itself on a sound scientific basis." Among recent utterances by foreign clinicians we may quote Kussmaul, who insists that "the treatment by water has passed its childhood days. It has won for itself a steadily growing confidence as a remedial agent."

The laudations of hydrotherapy by some of its advocates have at times justly created doubt and distrust, and its adoption as a universal panacea by the hydropaths has estranged conservative physicians. Moreover, there existed no scientific basis for hydrotherapy before Winternitz. To prevent this remedial agent from again lapsing into disuse it would seem necessary that the principle and method of its application be made a distinct part of the college course. As water differs from all other remedies now taught in the lectures on therapeutics, it requires special apparatus for demonstration of its physiologic and therapeutic effects. In the discussion of Professor Putnam's essay Dr. Rogers said jocosely but truly that "medical colleges ought to cease to graduate men who don't know the difference between a Scotch douche and a hot Scotch," and Dr. Coggeshall insisted that "it is almost disgraceful that students should be allowed to graduate from our medical colleges with practically no systematic teaching in regard to non-medicinal therapeutics." Kussmaul writes: "Of hydrotherapy the young physician knows almost nothing. Here is a great gap in the education of our physicians; here is the real cause of his inability to cope with the empirics for the favor of the public. A revision of our course of study must be made above all things. A distinct chair and a clinical division are required in which appropriate cases may be treated by hydrotherapeutic procedure, but this professorship should not be connected with that on pharmacology." Professor Vierordt feels warranted in "the recommendation that facilities for ambulant hydriatric treatment should be connected with every medical polyclinic for the benefit of patients and stu-

dents alike." Professor Credé of Leipzig, claims that "if physicians were better versed in these branches, the field of operation of many quacks would be greatly curtailed." Hence, Dr. Foster says truly: "it requires only a very ordinary everyday seer to foretell that hydrotherapy must very soon be introduced into our leading schools of medicine as a regular branch of our curricula. This will result both from the growing sense of its value, and because it should be as largely as possible in the hands of the general practitioner and not exclusively with the specialist."

This brings us to another cause of failure of acceptance of hydrotherapy by the profession, *viz.*, its active adoption by laymen in recent years. This is but a repetition of history. "Father Kneipp" followed the methods of Pater Bernardo who preceded him more than a century; and the peasant Priessnitz, who preceded Kneipp a half century, advocated the methods of the parson Hancock who wrote on water as "febrifugum magnum" in 1723. To day the "Naturarzt" represents these empirics. His ranks are recruited from among clerks, merchants, teachers and students who, having failed in their chosen calling, become masseurs or bath-nurses, and graduate into "Nature-doctors" when they have the means to open an institution and advertise themselves. Thus far this class of semi-doctors has not become a positive disturbing factor in this country. That their encroachment is not distant is evident from the fact that institutions of this kind already exist in New York, New Orleans, and perhaps elsewhere. These are "run" by bath nurses and masseurs whose specious promises inveigle some medical men into employing them. Until physicians become familiar with the prescriptions of the various hydriatric procedures, and until nurses are trained to fill such prescriptions, as druggists do in their branch, it would seem important that only institutions supervised by educated physicians be resorted to for hydrotherapy. Malpractice by bath-nurses who are unfamiliar with the principles of hydrotherapy has come under our observation. Their prescriptions are analogous to the counter-prescribing of druggists.

Professor Putnam justly deplores the fact that "there is no institution in Boston under the guidance of a physician to whom one may send patients with the confidence that they will be judiciously treated" In New York, Chicago and Philadelphia such institutions exist, and it is probable that the recently developed interest in hydrotherapy will lead to their establishment elsewhere. Thorough instruction in this subject in our medical colleges, and the management of institutions by educated physicians, will establish water as a remedial agent upon an enduring basis.

MOSQUITOES AND OTHERS.

We are accustomed to regard insect plagues from the purely perverse standpoint of our subjective inconvenience, tacitly believing that their own attitude is like that of the ubiquitous small boy, who

"Only does it to annoy,
Because he knows it teases"

But science is constantly revealing to man his state of dependence on the most trivial things. Some years ago it was discovered that sipping honey was not a mere butterfly pastime, but an economic factor in the world's food supply, and that without the intervention of myriads of different insects that transferred the pollen, many fruits, vegetables and crops would never mature. Now it is demonstrated that diseases are winged; or at least very many of them need the aid of a pair of wings, or a good pair of hoppers, to get from one person to another It is not only the malarial laden mosquito that serves as a transmitter of disease, but very many of the particular and private pests of man and domestic animals may be the bearers of contagion. In the light of this hint it is not surprising that the culmination of the ten plagues of Egypt was the entrance of the death angel in the land.

The simplest method of infection is allied to that by which insects fertilize flowers. Flies, not necessarily biting flies, but those of the scavenger order and the common house-fly, get their legs covered with the bacteria of cholera, typhoid and plague as they light and crawl on the sick or dying and the utensils used by them, and then immediately transfer the infectious matter by alighting on the food prepared for well persons.

The method of transmitting malaria and Texas cattle fever is a more complicated process. Here insects act not as mere conveyers but as intermediary hosts of the disease. The ingenious methods of experimenters are very interesting, and a combined spirit of martyrdom and love of the chase must have been

necessary to get at the evidence in the case of mosquitoes and ticks of Texas fever, to say nothing of the fleas that have been found to carry the plague from sick rats to human beings.

The subject is worth the critical and historical study which has been made of it by George T. Nuttall, M.D., Ph.D., and admirably presented in the last *Johns Hopkins Hospital Reports*. He has given a remarkably able résumé of the subject, showing that many other diseases such as anthrax, hog-erysipelas, chicken-cholera, yellow fever, tuberculosis, leprosy, Egyptian-ophthalmia and Florida "sore eye" are spread by the aid of vermin and flies. An immense amount of research work has been done along these lines, as may be seen from his extensive bibliography appended. The exact species and the habitat of the infecting vermin or insect have been determined, and the conditions of soil and climate have been studied with the result, that if the combination of mosquito netting and a kerosene-can will prevent malaria, it may be hoped that some equally simple and efficacious method may be found to stamp out various other plagues of cattle and of humanity.

ECHOES AND NEWS.

Plague Bacillus Found. — Dr. W. H. Park announces that the bacillus of the plague has been found in culture in both of the cases taken from the plague ship "J. W. Taylor."

Marine-Hospital Appointments.—On November 23d the President appointed Drs. Robert L. Wilson, Clarence W. Wille, Elmer R. Edson, and John W. Amosso to be assistant-surgeons in the United States Marine Hospital Service.

The American Hospital-ship "Maine."—Up to November 23d the fund for fitting out the "Maine" as a hospital-ship exceeded $90,000, exclusive of the receipts of the concert directed by Mrs. Brown-Potter. At the meeting of the executive committee of the fund on the above date three American surgeons and five nurses presented themselves and were cordially received by Lady Randolph Churchill and her colleagues.

A Barber Law in Missouri.—All the other progressive States might well follow the example set by Missouri. She has passed a "barber law" which requires that a barber must pay $1 to a Board of Examiners for certifying to his competency, that solutions of carbolic acid shall be used in the disinfection of razors, that sterilized towels shall be used, and that in other ways cleanliness and sanitation shall be observed.

Smallpox in Kentucky.—Smallpox has broken out in several counties of Kentucky. According to the statement of Dr. J. H. McCormack, secretary of the State Board of Health, there are in Uniontown, whose population is 1800, five hundred victims in various stages of the disease. The authorities in this and other towns seem to have concealed a really serious state of things. Uniontown, the source of the epidemic, has at last been placed in absolute quarantine and the entire State is urged to enforce general vaccination.

Diphtheria in New Jersey.—There is an epidemic of diphtheria in Montclair which is, however, fast subsiding. Up to November 26th there were twenty-two cases in the town. Two public schools and the parochial school connected with the Church of the Immaculate Conception were ordered to be closed on November 27th. In Newark there have been 126 cases reported during November with 11 deaths. During the same month of 1898 there were 140 cases. The disease is not confined to any portion of the city.

A Manila Hospital.— The Auxiliary Society of Trained Nurses has done excellent work in the Philippines. This Society must not be confused with that of the Red Cross. It is supported by wealthy New York citizens, and the nurses are not paid by the Government and are, indeed, not in the government employ at all, except as volunteers. There are twenty-seven nurses in charge of Miss Henschall, who was head nurse at one of the large military hospitals during the Spanish War. The Society supplements the work of the Hospital Corps.

Privileged Communications.—The *Lancet*, in commenting on privileged communications, observes that in a recent French case at Besançon, the Court declared that neither the consent of the patient's heirs nor anything else could free a medical man from the obligation to keep secret the disease for which he had treated the patient. This is of the same tenor as the law in this country. In England, on the other hand, physicians and surgeons may be compelled to disclose communications made to them by their patients in professional confidence.

Faith-Healers Outwitted —S. P. Linberger, a Christian Scientist, died at Wooster, Ohio, on November 23d. He had refused medical aid. After his death it was discovered that his son was sick with typhoid fever, and that the other members of the family would not permit a physician to be called. The young man's associates called the attention of the Probate Court to the case, and Judge McClarran promptly appointed a guardian for the young man, with instruction to procure at once a physician and a competent nurse, and to see that the medicine prescribed was administered.

Medical Students Suspended.—The entire senior class of the Medical School of Boston University was suspended from all recitations and lectures by the Faculty on November 25th. The cause was the boisterous conduct of

the class on two occasions when they were on their way to attend clinics at the Westborough Hospital for the Insane. This conduct was reported to the hospital authorities, who made complaint to the school, charging the class with insubordination, and refusing to allow them to continue their clinical work at the hospital. Dr. J. B. Sutherland, Dean of the school requested an apology, which was refused. The suspension of the students followed.

Progress of the Plague.—According to latest reports of the Marine Hospital Service 25 cases of plague have been reported from Santos, Brazil, with 10 deaths. On October 14th the mail steamer "Peninsular" disembarked at Plymouth a colored fireman who had been taken ill on October 9th with plague en route, also the sick man's attendant. Both were placed under sanitary police surveillance on the hospital ship "Pique" lying off Plymouth. The mail steamer left Plymouth for London. According to last advices no further cases had developed on board. From November 4th to November 11th, 11 fresh cases and 7 deaths were reported from Oporto, making a total of 236 cases and 81 deaths. The suspected cases of Delagoa Bay have been confirmed. This is of importance since through this port most of the present traffic to the Transvaal is passing and the danger of plague complicating the South-African War is not very remote.

Deaths of Dr. Prentiss and Dr. McMurtrie — Dr. D. Webster Prentiss, a lifelong resident of Washington, D. C., and a well-known physician and naturalist, died in that city on November 20th, aged fifty-six years. He was a member of many medical societies. He wrote much on medical subjects, and he was the author of a valuable work on the song and game birds of Maryland and the District of Columbia. During the Civil War he served as a surgeon in the Union Army. Dr. Daniel McMurtrie Medical Director in the Navy, retired, died in Washington, on November 21st. He had been in ill health for nearly a year, but was able to attend to his duties in the Navy up to the time of his regular retirement several months ago. He was sixty-three years old. He was graduated from the medical department of the University of Pennsylvania and he entered the United States service in 1861. He served in many important naval engagements. Several years ago he was Fleet Surgeon on the Asiatic station.

Sugar Diet for Troops.—Germany has completed elaborate experiments with sugar as a food for troops. The object was to test the advantages of a sugar diet in cases where great exertions were to be made within a brief period of time. According to the reports of experiments in various army corps a favorable result has been secured. It is considered proven that a sugar diet increases muscular power in a comparatively short time, considerably shorter than does egg-albumen. The effect of the latter, however, is more lasting, though sugar has the advantage of being much cheaper. The great rapidity of sugar absorption explains its rapid effect on the nervous system, which is a matter of great importance in all cases where speedy recuperation is desired, as in long-distance marching. Artificial substitutes for sugar, such as saccharin, have not the same effect. These experiments were conducted by Professor Pfuhl, head of the Physiological Laboratory of the Army Department, and Professors Senator and Muck of Berlin University. Possibly these findings may induce General Sternberg to modify the ration of our troops in the Philippines, which, according to Dr. Seaman, is the same as that supplied our troops in Alaska.

The Organization of the Acting Assistant-Surgeons of the United States Army.—A mass-meeting of the Acting Assistant-Surgeons of the United States Army during the Spanish War will be held at the armory of the Seventh Regiment, N. Y. N. G., Lexington avenue, New York City, on Tuesday, December 5, 1899, at 2 o'clock, P.M., for the purpose of organization, and to secure legislation by Congress doing justice to them and their interests, as follows: "(*a*) To give each the assimilated rank, pay, and emolument of a first lieutenant (staff) upon and for the date of muster-out, thus legally fixing his *status* as an *officer* of the army. (*b*) To give to each, comformably to the admitted verbal agreement and intentions of the Surgeon-General's Office, full payment for properly granted leaves of absence. (*c*) To give to each the commutation of quarters (when government quarters were not found) which was originally both stipulated and allowed, but afterward cut off. (*d*) To give to each the mileage and travel pay originally promised and enjoyed, but later by unjust discrimination disallowed and retracted. (*e*) To give to each the same rights and eligibility to pensions and to land and other emoluments that attach to assistant-surgeons of the United States regular or volunteer army. (*f*) To give to each the same allowance of extra pay that was given to officers and men of the United States volunteers in the late war, *viz.*, one month's extra pay for service in the United States and two months for service beyond seas. (*g*) To give to each preference for appointment (over those who have not had previous service) in the Medical Corps of the Army and Navy, and the Marine Hospital Corps of the United States, etc." It is truthfully claimed that the burden of the medical and surgical work of the Spanish War was borne by the nearly 1000 acting assistant-surgeons of the army, who were usually competent, devoted, and brave, dealing often and successfully with new forms of disease and great sanitary problems. They sometimes died on the firing line, but more often of disease, being always and everywhere exposed, overworked, and ill-fed. Theirs was only the shadow of rank and authority, and, though poorly paid, they were later deprived of part of their stipulated compensation by the narrow rulings of Treasury officials. No one can honestly question that they have deserved well of the country and are clearly entitled to the benefit of the contracts made with them, to honorable recognition, and the same consideration in every respect given to those of like position in the staff corps of volunteers and regulars, whose full duty and responsibility they ably performed.

MEDICAL MATTERS IN NEW YORK.

DEATH OF DR. WALLACH—SOFT COAL A NUISANCE—FOR BETTER TENEMENTS—HOME FOR CONSUMPTIVES—WOMAN'S HOSPITAL WORK—TAKEN TO MANY HOSPITALS—AMBULANCE DELAYED THROUGH MISTAKE BY POLICE—DR. DOTY'S RETURN—MISSIONARY WORK DONE BY THE NEW YORK COUNTY MEDICAL SOCIETY.

DR. JOSEPH G. WALLACH died in this city on November 21st after a long illness. He was forty-four years of age and a graduate of Bellevue. Dr. Wallach was a Director of the Educational Alliance of this city and a member of the New York County Medical Association.

The Appellate Division of the Supreme Court, Kings County, has affirmed the judgment of the County Court in a suit brought to recover damages from the Nassau Electric Railway Company for using soft coal, in contravention of the laws of 1895, which proscribes its use within certain city limits. It was held that it is well within the police power of the State for the Legislature to declare that the burning of soft coal within certain prescribed limits of the city is detrimental to the public welfare, and should be prohibited under authorities cited.

One of the features of the tenement-house exhibition to be held in this and in various other cities in January next will be a competition by architects for plans of model tenements. It is hoped thus to stimulate the interest of architects in the planning of houses for low wage-earners, and to show that such buildings erected with the object of obtaining a maximum of light and air can be made to pay the owners. Prizes will be offered, ranging from $500 down to $100, for the best plans. All plans submitted must provide for plenty of air, and there must be no damp, narrow courts. Prize plans will be exhibited at the Paris Exposition in 1900. The jury of award of prizes is composed of W. Bayard Cutting, I. N. Phelps Stokes, W. R. Mead, Miss Lillian Duald, John D. Crimmins, E. R. L. Gould, and Mrs. Roland C. Lincoln.

The Board of Directors of the Montefiore Home will erect a new sanatorium for poor consumptives at Bedford Station, in Westchester County, N. Y. The new building will cost $150,000, and will be devoted to the treatment of indigent consumptives. It will contain all modern and scientific improvements. The site selected is 410 feet above sea-level, overlooking the hills of Bedford.

The forty-fourth anniversary of the Woman's Hospital at Fiftieth street and Lexington Avenue was observed on November 23rd. Many well-known gentlewomen were present. Drs. Joseph D. Bryant, Henry D. Nicoll, Clement Cleveland, Horace Tracy Hanks, and John Duncan Emmet were among the representatives of the medical staff. According to the annual report of John E. Parsons, Esq., the President of the Board of Governors, the total number of patients treated in the indoor department was 863, of whom 267 were free patients. It is expected that a new hospital, costing four hundred thousand dollars, will be built.

The hospital system which makes the following occurrences possible should certainly be changed: Bridget Murphy on November 13th fell through the trap-door on the roof of her house to the floor below, fracturing her skull. She was taken to the J. Hood Wright Memorial Hospital, where she was kept for two days. Then she was hurriedly transferred to Harlem Hospital, whence she was again transferred to Bellevue and finally to the City Hospital where she died. The autopsy of Dr. Weston, Coroner's physician, revealed meningitis and a fracture at the base of the skull. Dr. Weston volunteered the opinion that the patient would not have died from her injuries had she not been removed so often. John Cunningham, 70 years old was struck by an electric-car and was taken to Harlem Hospital on November 20th. Later he was transferred to Bellevue. The Bellevue authorities wished to retransfer him to the City Hospital, but his family called at the hospital and protested. They took him home in a cab, and he died soon after.

Whenever the ambulance system in this city is not found quite perfect, it is the surgeons who are invariably held blameworthy. In the following instance the police were clearly at fault: The Harlem Hospital was notified at 7 A. M. to hurry an ambulance to 543 East 143d street to attend a woman who had jumped from a third story window. Ambulance Surgeon Muller went at once to that address but found no patient. On his way back to the hospital he passed the East 138th Street Police station where he learned that the injured woman was at 543 East 134th street. He went at once to the place, and found the patient, who died soon after he reached her. The mistake caused an hour's delay. Had he been given the correct address at first it is very possible he may have saved the woman's life.

Health Officer Alvah H. Doty arrived home on November 25th. During his seven weeks absence he observed the methods in operation in Europe for the inspection and transportation of intending immigrants to this port. Dr. Doty gave unqualified approval to his deputies, Drs. Sanborn and L'Hommedieu, for their management of the plague cases at quarantine.

Dr. Doty, while in Europe, visited German ports, and went also to St. Petersburg, Moscow, Warsaw, Rotterdam, and other ports of embarkation in the low countries. Concerning Russian immigrants Dr. Doty found that they came from densely settled communities, and that they are subject to close supervision. No person can leave his home to go to another locality without a passport. If any epidemic breaks out in small villages a cordon of Cossacks is put on guard, the town is burned, and the inhabitants are provided with new clothes. All Russian inspections are thorough.

On the German frontier are six points of inspection to which the railways bring the immigrants, who are put into barracks and subjected to the inspection of a medical officer. At these points all those who fail to come up to the standard required by the United States immigration laws are sent back. Each of these inspection stations are provided with disinfection plants, detention barracks, and have medical examiners in attendance

About six miles outside of Berlin is a place to which those from the six frontier stations are sent. This is called a control station and is maintained at the expense of the steamship companies which are banded together to maintain an inspection service to prevent the embarkation of undesirable persons. From the control station the immigrants are sent to the point of embarkation, where another rigid inspection is made. At this inspection there is a United States consular officer always present. Dr. Doty received every courtesy from the officials he met, and special offers were made him to inspect stations, hospitals, laboratories, etc. He was astonished, he said, at the excellent systems prevailing generally.

The following summary of work accomplished by the Medical Society of the County of New York, through its Council, in suppressing illegal practice in this city, speaks for itself: During the year ending October 1, 1899, there were 45 new prosecutions, 33 convictions, 17 cases otherwise disposed of, and 11 left pending. In fines $2425 were imposed and $2075 collected. The total expense amounted to $2867.40.

MEDICAL MATTERS IN PHILADELPHIA.

[From Our Special Correspondent.]

SECTION ON OPHTHALMOLOGY, COLLEGE OF PHYSICIANS OF PHILADELPHIA—PHILADELPHIA COUNTY MEDICAL SOCIETY—$5000 APPROPRIATED TO STAMP OUT SMALLPOX—SALARIED SCHOOL INSPECTORS—THE MEDICAL AND PHYSICAL CAUSES FOR NON-ATTENDANCE IN THE PUBLIC SCHOOLS—STUDENT GOVERNMENT AT JEFFERSON—ST. MARY'S HOSPITAL—DR. SIMON FLEXNER—DR. S. WEIR MITCHELL—HEALTH REPORT FOR THE CURRENT WEEK.

PHILADELPHIA, November 27, 1899.

DR. G. E. DE SCHWEINITZ reported a case of "Gumma of the Iris and Ciliary Body, with a Histological Study of the Enucleated Eyeball," at the last meeting of the Section on Ophthalmology of the College of Physicians of Philadelphia, held November 21st. The patient was a woman of forty-eight years, who had been treated for secondary syphilis at the Philadelphia Hospital, from which institution she had been discharged after the disappearance of the symptoms. In May, 1898, she was again admitted, having complained for three weeks of an acute inflammation of one eye. Iritis was pronounced; there was a yellowish-white new growth on the upper part of the iris, and the lower part of the eye contained a mass of broken-down whitish material. The patient was placed on protoiodid of mercury, mercurial inunctions, and large doses of potassium iodid, under which treatment the broken-down granulomatous material disappeared from the lower part of the eye; the condition of the eye, however, was such that enucleation was indicated, which operation was done on June 27th. It was ascertained that a gumma sprang from the anterior part of the ciliary body and involved the iris. The cornea was normal, except where it overlaid the gumma. The half of the iris not included was infiltrated with round cells, being attached by total synechia to the capsule of the lens, which was also infiltrated with gummatous tissue. The retina was approximately normal.

At the same meeting Dr. Burton K. Chance presented by invitation a communication on the "Clinical Study of Twenty-two Cases of Epidemic Cerebrospinal Meningitis, with Especial Reference to the Ocular Symptoms." The cases observed were among the 37 treated at the Municipal Hospital during the epidemic of cerebrospinal meningitis in this city last January. The majority of the cases were first seen during the second and third week of the disease, some of the patients were stuporous, others exceedingly irritable, and still others were found in strong opisthotonos, all of these complications rendered ophthalmoscopic examination very difficult. Among the subjective symptoms the most conspicuous were photophobia, burning pain in the eyelids, and in one case unilateral ptosis. Visual tests showed varying conditions—2/100, 2/60, 9/50, and so forth. There was internal squint in two cases, and marked choked disc in one. In many cases congestion of the optic disc and retina was observed. No hemorrhages were noted, but in some cases the lymph-sheaths around many of the vessels were distended. There were 15 deaths among the whole number of cases treated at the hospital, and 8 from the series reported by Dr. Chance. No post-mortems were made. Among the fatal cases was the patient with choked disc. Owing to the fact that none of the patients who recovered reported subsequently for examination, the permanent effect of the disease could not be studied. In a single case seen at the Will's Eye Hospital, the patient had double choked disc, and gave a history of an attack of cerebrospinal meningitis during the same epidemic in this city.

At the last meeting of the Philadelphia County Medical Society, held November 22d, two interesting papers were read on the topic of skiascopy in pulmonary diseases, by Dr. Wm. S. Newcomet, and by Dr. T. Mellor Tyson. Dr. Newcomet's paper, on "The Use of X rays in the Study of the Lung," demonstrated the value of the Roentgen-rays as a means of verifying conclusions reached by other clinical methods, but also showed that the method by no means sets aside the older and more dependable methods of diagnosis. As a contradiction of the belief held by some that dense structures alone are visible with the X-rays, Dr. Newcomet showed a radiograph of a handkerchief in which the folds and creases were visible. Contrast is needed in this work, and a weak light may give a shadow where a strong light would penetrate, showing nothing. Where dulness on percussion is obtained over the chest the underlying consolidation may be seen with the fluoroscope. Cavities are recognized in the fluoroscopic image as circular spots with a bright center, and a surrounding darker zone. Old pleuritic thickening over an area of consolidation shows as an intense blurring darkening.

Dr. Tyson, in a paper on "The Practical Use of the Fluoroscope and Radiograph in Lung Diseases," expressed the conviction that the use of these aids in diagnosis was a great help in arriving at early diagnosis in diseases of the lungs, the fluoroscope being especially

useful in most instances. It should be used in all cases where there is the least doubt regarding the diagnosis and where cavities are present its intelligent application will in many cases give a better idea of the extent of the cavity than can be obtained by any other method known to clinical medicine. A number of cases was detailed to show the ease and certainity with which the skiagraph and fluoroscope located areas of consolidation and cavities, the presence of which had been later demonstrated by other methods of physical examination.

A special appropriation of $5,000 has just been passed by the State Legislature to be devoted to stamping-out the smallpox outbreaks in different parts of this State. It is confidently expected that Governor Stone will sign the bill at any early date, so that the money may at once become available.

A resolution has been adopted by the Board of Education urging Councils to appropriate the sum of $45,000 for the purpose of making possible a daily inspection of the public schools, by of special corps of physicians, each of whom will receive a salary of $300 per year. The subject is also being taken up by the County Medical Society, and the following committee from this body has been appointed to confer with the authorities on the matter: Drs. J. Madison Taylor, W. W. Keen, Wm. Campbell Posey, H. F. Anders, S. D. Risley, L. S. Somers, Lawrence Flick, and Dr. Thos. B. Fenton.

Statistics just made public regarding the physical and mental causes for non-attendance at the public schools of minors between the ages of 8 and 16 years show the following etiological factors among the 9985 children included in the census: Mentally incapable, 111; blind, 37; deaf and dumb, 45 otherwise physically unable to attend, 664. The non-attendance of the other children is accounted for by other causes not relating to their physical and mental conditions.

The Faculty of the Jefferson Medical College has inaugurated a system of student-rule at this institution, similar to that prevailing at other institutions of learning, notably at Cornell, Princeton, and Columbia Universities. In compliance with the desires of the Faculty, a Student's Committee has been formed, composed of the four class-presidents, and 16 other members chosen to represent the different classes. To this committee the Faculty is to refer for adjustment all questions of disorderly conduct among the students, questions of damage to college property, and other infractions of the rules,

The management of St. Mary s Hospital has acquired property adjoining the present hospital building, upon which it is proposed to erect next spring a large addition to this institution. The present hospital contains about 100 beds, but the proposed extension will provide accommodations for double this number of patients, besides admitting other needed improvements.

Dr. Simon Flexner has been installed as the new patron of the John Guiteras Medical Society of the University of Pennsylvania as the successor of Dr. Guiteras whose chair Dr. Flexner occupies.

Dr. S. Weir Mitchell delivered during the past week two lectures on "The Conduct of Life" before the upper classes of the Girls' High School.

The total number of deaths in this city for the week ending November 25th was 386, being an increase of 21 over the number reported last week, and a decrease of 63 from those of the corresponding week last year. Returns of contagious disease were made as follows: Enteric fever, 43 cases, 4 deaths; scarlet fever, 72 cases, 4 deaths; and diphtheria, 127 cases, 24 deaths.

MEDICAL MATTERS IN CHICAGO.

[From Our Special Correspondent.]

ANNUAL REPORT OF EVANSTON HOSPITAL—VIOLATORS OF MEDICAL PRACTICE ACT—VITAL STATISTICS—REPORT ON CHILD STUDY—CHICAGO PHYSIOLOGICAL SCHOOL FOR NERVOUS AND DELICATE CHILDREN — MEASLES AND WHOOPING-COUGH ADDED TO CATEGORY OF CONTAGIOUS DISEASES —WORK OF ILLINOIS SOCIETY FOR THE PREVENTION OF CONSUMPTION—CHICAGO MEDICAL SOCIETY—VESICO-RECTAL ANASTOMOSIS.

CHICAGO, November 27, 1899.

THE eighth annual report of the Board of Directors of the Evanston Hospital has been issued. It is the first report that has been issued since the occupancy of the new building by the hospital, and reviews the work of the first complete year in the new quarters. The various reports of the officials show that the hospital is in a flourishing condition, and many plans are in mind for the enlargement of the scope of the work for the future. The attendance at the monthly meetings has shown a higher average than any previous year. A total of 2224 calls were made during the twelve months on 298 patients. The money and donations that have been so freely given have been well placed, and the directors hope that in the future it will be possible to place more nurses on infectious cases, and to have a nurse to carry on the work during the vacation months.

The attorney for the State Board of Health, Mr. Barnes, finds it extremely difficult to convict violators of the Medical Practice Act. He declares that such violations are numerous, that one cannot take a street-car ride without observing their signs on either hand. Juries are slow to find verdicts of guilty even where the evidence is conclusive. Every encouragement should be given the prosecutor for the State Board of Health both in his treatment of unsanitary lodging-houses and in his handling of medical montebanks. On the other hand, his procedure in every case should be so well defined and aggressive that there would be no room for doubt on the part of the offender that the prosecution was sincere, and that one conviction, if the violation did not cease, would be speedily followed by another, with the added penalty for a second offence.

Little change in public-health conditions is noted in the weekly bulletin of the Health Department issued on the 20th. There were 451 deaths recorded last week from all causes, but the excess of 11 over the previous week is due to the return of belated coroner's certificates, 5 being the victims of the New England mills explosion. Little

abatement of the diphtheria and scarlet-fever mortality is shown. Deaths from diphtheria were 24, the same as the previous week, and 9 more than in 1898, and while there were 2 deaths fewer from scarlet fever last week than the previous week, there were 12 in excess of the corresponding week last year. The *Bulletin* says: "It is to be feared that the stationary mortality-rate from these diseases does not indicate the culmination of the epidemic, but is due rather to the unusually mild weather, which favors ventilation by allowing doors and windows to be kept open. Inquiry among physicians shows that there is no diminution in the number of new cases, and there is reason to fear that when the weather turns cold the death-rate will increase."

Dr. W. S. Christopher and the members of the Committee on Child study will have another report to present next month. Examinations are being conducted and much valuable information is being obtained. The improvements and innovations suggested by this committee for the better sanitary arrangements of the schools will be given due consideration by the Board of Education. The plan of Dr. Christopher for medical inspection in the schools has been amended to conform with an opinion from Attorney McMahon. The Board has no authority to exclude children from the schools except in cases of emergency. The amendments, as offered by Dr. Christopher, restricted the resolution to cover cases of emergency, when the pupil may be debarred from school, the former reading being that the pupil having been absent four days should be detained twenty-four hours pending examination. The emergency provision was held to be in force at present on Dr. Christopher's statement that diphtheria has crossed the line of epidemic. The medical inspectors will number fifty, and will receive $50 a month for the time they are on duty.

Part of the training work of the Chicago Physiological School for Nervous and Delicate Children will be to fit nurses for duty with this class of children. This new departure has been taken up at the suggestion of Dr. Nicholas Senn.

Measles and whooping-cough have been added by the Health Department to the category of contagious diseases which must be reported by attending physicians.

The formation last summer of the Illinois Society for the Prevention of Consumption is to be followed this winter by an active campaign seeking legislative aid for the care and cure of consumptives. The organization by the City Council of a special milk-inspection department, which shall prohibit the sale of milk not previously certified as non-tuberculous, will be urged, and the State will be asked to erect a State sanatorium for consumptives. The State Board of Health will recommend the building of the sanatorium. Pamphlets explaining the dangers of the various forms of tuberculosis will be distributed, in order to educate the public regarding the spread of the disease, first among cattle, and subsequently among people. The officials of the Society believe that with the assistance of Mayor Harrison, Health Commissioner Reynolds, and Governor Tanner they will be able to pass legislative measures without difficulty. Following the establishment of the sanatorium, legislation will be asked for providing for the compulsory isolation of consumptives in virulent stages. It is a question whether consumption is spread more by consumptive cattle or by persons. It is believed the sale of milk from untested cattle is doing much to spread consumption. The idea of instituting a city inspection has been talked of by Dr. Reynolds and is favored by veterinarians. Dr. William A. Evans, a member of the Tuberculosis Committee of the American Medical Association, its preparing a report on the prevalence of tuberculosis in all parts of the world. The report probably will lead to making national in scope the movement for legislation for the eradication of consumption. It is believed that before long Congress will be asked to recognize the danger of the spread of consumption in this country, and to establish a national sanatorium.

At a meeting of the Chicago Medical Society, held November 22d, Dr. Jacob Frank demonstrated vesicorectal anastomosis, a new operation for exstrophy of the bladder, upon a live dog. This operation consists in anastomosing the bladder to the rectum by means of the Frank decalcified bone-coupler. The ureteral openings in the bladder are not anatomically interfered with, hence a fortification against ascending infection. Dr. M. Herzog made the pathological and bacteriological examinations, and the results were far more satisfactory than those of ureteral implantation, in which kidney infection resulted in every case. The conclusions drawn were: First, that the recovery of the dog and the macroscopical appearance of the tissue do not necessarily signify absence of infection; second, in dogs killed thus far the operation of vesicorectal anastomosis can be performed without a resulting kidney infection. At the same meeting Dr. Herzog also made a post-mortem examination of a dog operated on twenty-four weeks ago, and showed the condition of the urinary tract, which was very satisfactory.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

REPEAL OF THE DOG-MUZZLING ORDINANCE—CASE OF "THIRD-GENERATION" SYPHILIS—ARTIFICIAL EYELASHES—HOSPITAL SHIP OF THE AMERICAN WOMEN IN LONDON—SCHOOL-MEALS FOR UNDERFED CHILDREN—55,000 STARVELINGS IN LONDON—ALLEGED INCREASE OF INSANITY IN IRELAND—GOVERNMENT CARE OF THE "INNOCENT"—POPULATION OF WORKHOUSE AND CRIMINAL ASYLUMS ALMOST STATIONARY.

LONDON, November 19, 1899.

MUCH joy is expressed in the dog-loving circles over the repeal of the muzzling ordinance in London but this does not seem to be echoed very cordially by the medical profession. The practical disappearance of hydrophobia for nearly a year past, on the strength of which the ordinance was rescinded, was in all probability largely due to the muzzling precautions themselves, and fear is expressed that the new departure may be followed by a marked in-

crease. One boon the ordinance has certainly conferred upon the community is the practical elimination not merely of the stray and ownerless dog, but of the cur of all degrees. Over 30,000 dogs were captured in the first five months of its operation and of these but 6000 were claimed by their owners.

A most rare and unusual case, which we believe is almost unique in surgical annals, was presented by Mr. Jonathan Hutchinson at his clinical demonstration at the "Polyclinic" this week. This was a syphilitic child born of and accompanied by a mother who herself presented unmistakable signs of inherited syphilis. As Mr. Hutchinson declared the nature of the disease in both mother and child to be absolutely unmistakable, there can be little question as to the certainty of the diagnosis, and as the mother by virtue of the hereditary infection would be immune to the disease, the probability would be that the infection came directly from the father. He unfortunately, however, was not present nor could, under the circumstances, any conclusive history of the occurrence of the disease in him be obtained, but the possibility of a transmission to the third generation is so extremely remote that Mr. Hutchinson is strongly of the opinion that this must have been the method of infection.

The possibilities of cosmetic surgery are only just beginning to be realized, according to our lay contemporaries. One of them has discovered another method of adding to the attractiveness of the human face by the insertion of what it terms "artificial eyelashes." These are manufactured by the delightfully simple process of passing a needle threaded with hair through the lid and out at its edge and then cutting off one end of the hair close to the skin, and the other at such distance from the edge of the lid as may be desired to make the eyelash. The journal, however, does not report or even supply photographs of any actual cases of this interesting embellishment; and in view of the fact that at least twenty or thirty such stitches would have to be taken to make even a decent imitation of a row of eyelashes and that the hair threads would cause intense irritation from the very start and be almost certain to result in a beautiful crop of styes within forty-eight hours, to say nothing of such a minor detail as the impossibility of getting the downward slope given by such a method of introduction converted into the beautiful upward curve that is required in an eyelash, we may be pardoned for exercising a good deal of healthy scepticism on the subject. We fully admit the truth of the old saw that "pride feels no pain," but we honestly doubt whether this painful procedure could ever be carried out with success. The journal in question cites an alleged *Médécine Française* as its authority for the statement.

The generous scheme of the American women in London to supply a hospital ship for South-African service is developing with genuine Transatlantic rapidity. One of the great steamship lines, the Atlantic Transport Company, has placed at their disposal a ship which by a double coincidence is curiously appropriate for the service, first, in that its name is "The Maine," and second, that it is the twin ship of the "Missouri" which was fitted out for the same purpose during our Cuban campaign. Offers of assistance come in from every hand. The well-known chemists, Burroughs & Welcome, have volunteered to provide the entire equipment of medical stores, and abundant contributions have been received from the members of the society and other Americans resident in London.

A gratifying proof of the growing influence which medical and hygienic opinions are coming to exercise in educational circles is afforded by the serious discussion of the London School Board of a proposition to make formal provision for providing school-meals, for underfed children under their instruction. It has long been vigorously urged by our profession, first, that the greatest care should be taken to see that no actual physical defects prevented school children from making use of the instruction offered to them, and, second, that their physiological condition as to supply of food and sleep must be carefully watched, in order that teaching, no matter how admirable, may be either grasped or retained by the pupils. In the terse and homely phrase of Luther they have insisted that "empty belly hath no ears." Formal provision for school-meals has been made in several of our American cities, and a voluntary association for the same purpose is already in existence in London with a number of similar local societies more or less under its control. But the urgent need of the whole scheme is that of bringing it under one central authority and providing some means of preventing imposition by non-deserving pupils upon this noble and admirable charity. The urgent necessity of such a movement can be seen in the report of the existing Society to the effect that no less than 55,000 children in London alone go to school so insufficiently fed as to be practically unable to profit to any reasonable extent by the instruction offered them. It is one of the most hopeful indications in the New Education that the physiological basis of brain work and the high value of expert medical advice in every department of the executive arrangements of the school are given a leading if not a foremost place. The day is rapidly approaching when a school physician will be regarded as indispensable as a school teacher.

The lay press is making much mournful capital out of the steady increase of lunacy in Ireland, as apparently demonstrated by the reports of the inspectors for the current year. These, upon the face of them show a gross increase of over 7000 registered lunatics in the past nineteen years, or nearly 60 per cent. This would give a steady increase of about 3 per cent per annum, which was almost the exact increase registered in the year 1898. In the mass these figures are undoubtedly alarming, but when we come to analyze them more carefully we see that a large percentage of this increase is simply another illustration of the general process which has been taking place in the spread of civilization, and the introduction of more humane and efficient methods of care for these unfortunates. It will be remembered that for a number of years the increase of insanity in England and Wales was a fruitful source of alarm to statisticians of a pessimistic turn of mind, but this is now generally recognized as having been simply

due to the steady and desirable process of bringing lunatics, who were formerly permitted to remain with their families or even to wander about the country as beggars and objects of charity, within the doors of appropriate asylums. This is supported by the fact that for nearly three years past the percentage of lunacy has remained almost stationary, indeed in some parts of England has begun to diminish. Ireland is of course, in most respects, anywhere from a generation to a century behind either England or Scotland in her social organization, and is now beginning to pass through the same stage which has already been surmounted by the sister countries. Another element which cuts an important figure in this connection should also be borne in mind, and that is, the singular and touching attitude assumed toward these unfortunate individuals by the bulk of the Irish peasantry. The lunatic is still looked upon as a "changeling" or individual bewitched by the gods or the fairies, and to a considerable degree under their special protection. Even his name has been softened down to the almost affectionate pseudonym of "*innocent*" and far from being an outcast from the community he is kindly treated and even a welcome guest. The blessing and the curse of an innocent are both regarded as peculiarly potent, and the latter is especially to be dreaded. Hence the recognition that the poor "natheral," or "object," is really the victim of disease, and as such ought to be confined in an appropriate hospital is extremely slow of acceptance by the Irishman.

The great bulk of the increase recorded is in the population of the great government asylums, into which these unfortunates are being steadily gathered. The population of work-house asylums, representing the acute cases has remained almost stationary, as also that of private establishments, while the number of the criminal insane has slightly diminished.

HEMORRHAGE IN CASES OF JAUNDICE.

To the Editor of the MEDICAL NEWS:

DEAR SIR:—In the discussion on Richardson's paper reported in your issue of November 25th, no reference was made to the importance of taking the coagulation time of the blood in cases of chronic jaundice prior to operation. The tendency to bleeding in these cases is well known, and the capillary oozing, sometimes so serious after or at operation, is probably due to the marked impairment of the power of coagulation in some cases. We have found the coagulation time to be ten or twelve instead of the normal three or four minutes. Wright's tubes for taking the coagulation time are easily procured, or in their absence a good-sized blood-drop on a slide may be carefully watched.

ABSCESS OF LIVER AT AN EARLY AGE—RESUSCITATION BY TRACTIONS OF THE TONGUE AFTER APPARENT DEATH LASTING FOR HOURS—TUBERCULOSIS MADE RAPIDLY WORSE BY CHILDBIRTH—RADICAL CURE OF HERNIA WITHOUT BURIED SUTURES—FISH AS TRANSMITTERS OF TUBERCULOSIS—SOME RECENT ADVANCES IN SURGICAL METHODS—OSSEOUS TUMORS—RESECTION OF MORE THAN TEN FEET OF INTESTINE—SPLENECTOMY AND SPLENIC LIGATURE—OBJECTIONS TO IMMOBILIZATION OF TUBERCULAR JOINTS.

AT the Academy of Medicine, September 19th, CADET DE GASSICOURT gave the history of a patient who was operated on at the age of two years for abscess of the liver. The abscess was opened wide, and about a pint of inodorous pus escaped. The cavity was washed with a solution of boracic acid and drained. The washing was repeated daily and recovery was prompt and satisfactory.

At the session of October 3d LABORDE mentioned fourteen new cases of the restoration of persons apparently dead by long repeated tractions upon the tongue. In one-half of these instances, the tractions were kept up from twenty to sixty minutes. One patient was worked over in this manner for three hours before he could be brought back to life. The exact time during which a patient may remain apparently dead and then be resuscitated has never been determined, either by experiments upon animals or by the treatment of the living, but from the results here quoted it is evident that resuscitation is possible after a much longer interval than one might at first suppose. By the old methods, when asphyxia had lasted more than five or six minutes, respiration could not be re-established. By tractions upon the tongue, however, persons have been brought back to life who were thirty or even forty minutes under water.

At the session of October 17th DOLERIS mentioned three cases which support the popular belief that childbirth hastens tubercular processes in the mother. One woman who had chills and hemoptysis, gave birth to a non-tubercular child at the sixth month of pregnancy. The child died in six hours. From the following day the mother grew rapidly worse with cough and abundant expectoration, the sputa containing tubercle bacilli. In two weeks she was dead. The autopsy showed extensive and active lesions in both lungs and in the intestine; but there were no miliary tubercles, thus showing that there had been a lighting up of old lesions, but no general infection through the blood. That this may also occur, was shown by another case which also terminated fatally. Blood from the heart of this patient, when inoculated into guinea pigs, produced tuberculosis. Thus in two ways childbirth may cause a rapid extension of the tubercular lesions.

At the Society of Surgery, October 4th, MONOD discussed Vanverts' method of curing hernia without leaving sutures permanently buried in the tissues. For the radica cure of inguinal hernia, the sac is exposed, ligated, and cut away. The spermatic cord remains behind the

abdominal walls which the operator is about to suture in a single layer. The needle is passed through skin, aponeurosis of the external oblique, and such portions of the internal oblique and transversalis as are available, and then it is passed outward through the opposite aponeurosis and skin. This is essentially the method employed by Villar and others to close laparotomy wounds. Of twenty patients operated upon by this method eleven were seen some time later. All of the eleven were free from recurrence, and the results were described as excellent.

At the Society of Biology, October 7th, NICOLAS and LESIEUR told of the results they obtained by causing young fish to eat sputum known to contain tubercle bacilli. After seven months the fish were killed and the bacilli were found to be present in every organ of their bodies which was examined. The muscular portions of these fishes were fed to guinea-pigs, and in the nodules and abscesses which formed in the bodies of the pigs tubercle bacilli were readily demonstrated.

The Thirteenth Congress of the French Association of Surgery was held in Paris from the 16th to the 23d of October. Professor Antoine Poncet delivered the address of welcome, during which he mentioned some of the more recent discoveries of surgical interest. With reference to the drainage of wounds he took the somewhat novel position that in every wound, no matter how carefully made, there is always a possibility that blood or serum may collect in some portion of it and give rise to future trouble if the skin unites by first intention. His conclusion therefore is that primary union should never be aimed at until a wound has been methodically drained, no matter how aseptic it may appear. No one ever regrets having drained a wound; he said on the other hand many surgeons have had reason to regret their attempts to secure primary union without drainage. Take, for example, a laparotomy for appendicitis in the interval. It it preferable to leave an open wound which may be tamponaded without pressure. In this matter infectious peritonitis with possible death is avoided, as is also the occurrence of a hematoma or suppuration of more or less gravity, requiring a re-opening of the wound and a delay in the final recovery. If this plan of treatment is desirable in the case of aseptic wounds, it is equally so of course if the character of the wound is doubtful. The question of disinfection of a wound must then also be raised. If a wound is known to be infected this question will naturally be settled in the affirmative.

POLLOSSON and BÉRARD discussed the question of osseous tumors. In spite of attempts to settle the etiology of tumors in general, it is still necessary to classify them solely by their histological differences. Skiagraphy, however, has furnished some points which aid the surgeon in assigning a bony tumor to its proper place. It is of assistance in distinguishing the epiphysial tumors from chronic osteomyelitis and from tuberculosis; in distinguishing diaphysial tumors from chronic osteomyelitis and from syphilis; in distinguishing encapsuled tumors from diffuse tumors, with or without pathological fracture; and, finally, in distinguishing tumors associated with formation of new bony plates from other neoplasms. The surgeon should accustom himself to the skiagraphic examination and should not rely simply upon photographs. This is especially true in the case of sarcoma with myeloplaques, the only variety of sarcoma in which a partial operation is justifiable. Skiagraphy is equally serviceable in determining the exact condition of patients who appear cured. The authors attempt to determine the average period of recurrence of different kinds of tumor after their removal. Round-celled sarcomata and malignant chondromata usually return in less than a year. If the patient is not operated on, spindle celled sarcomata will produce death in from one to three years; round-celled sarcomata in two years or less; osteo-sarcomata in a year or sixteen months; and malignant chondromata and epitheliomata in about a year. Amputation is sometimes indicated even if recurrence is almost certain to follow, for the reason that the patient under such circumstances is usually saved the pain and distress caused by ulceration, for death from dissemination of the tumor generally comes before the recurrence has time to undergo degeneration.

MONTPROFIT reported the resection of 3.1 meters (122 inches) of intestine from a patient who suffered from an inguinal hernia as large as the adult head. The hernia was irreducible and the intestine so bound together and to the surrounding tissues by adhesions that it was impossible to free it or to return it into the abdomen. It was, therefore, resected and the ends anastomosed laterally. Of the portion of intestine resected thirty-two inches were large intestine, comprising the cecum, the ascending colon, and a little of the transverse colon, while the balance was made up of small intestine. The patient recovered.

JONNESCO since 1896 has removed twenty-nine spleens either for hydatid cyst or on account of enlargement due to malaria. Ten patients died, two from hemorrhage and eight as a result of pulmonary complications. Experimentally, he satisfied himself that atrophy of the spleen cannot be obtained by complete ligature of its vessels. Under these circumstances the spleen rapidly becomes gangrenous. Ligature of the artery or of the splenic veins alone produces a slight atrophy, while ligature of the greater part of the pedicle produces a rapid atrophy. He also determined that if adhesions are produced between the spleen and the abdominal wall it is possible to divide its pedicle without fear of gangrene. It follows therefore that if at operations a spleen is found to be too adherent for removal one may safely divide its pedicle and allow it to atrophy.

CALOT said that in the treatment of white swelling, immobilization might be avoided and the lesion be attacked by injections into the joint cavity. As soon as the treatment of the tubercular focus is finished, that is to say at the end of four to six weeks, attempts should be made to develop the movements of the affected joint, using for this purpose apparatus made especially for the joint affected, and combining the treatment with daily massage of the atrophied muscles. In this manner one can obtain a real cure of a tubercular joint, removing the disease, and preserving the usefulness of the joint.

LUCAS-CHAMPIONNIERE said that the idea that an inflamed joint must be kept immobilised is a false one. A distinction should be made between functional rest of a joint and absolute immobilization. He strongly objected to putting a tubercular joint up in plaster. This mode of treatment is indicated only if pain persists. Otherwise injections of camphorated naphthol combined with mobilization form the best treatment. The speaker said that he could mention many successes of this method of treatment, one striking illustration being a case of a boy who from the fifth to the seventh year suffered from tibiotarsal tuberculosis, but who recovered so perfectly that he was able to perform his military duty.

SOCIETY PROCEEDINGS.

THE NEW YORK ACADEMY OF MEDICINE.—SECTION ON PEDIATRICS.

Regular Meeting, Held October 12, 1899.

HENRY KOPLIK, M.D., in the Chair.

DR. HENRY HEIMAN presented two interesting cases of nervous disease in children in which one of the principal symptoms was advancing blindness. In the first, a girl aged six years, rather large for her age, there were no symptoms except that she had never been very bright, and had not developed rapidly. Ophthalmoscopic examination showed that optic atrophy was developing. Her general health was good. In the boy the history is of rather more importance. He did not get his first tooth until thirteen months, but he learned to talk and walk at fourteen months. He fell about eight months ago against an iron railing, but it is doubtful if this was not rather an effect of his incipient blindness and ataxia than a cause of his present condition. The parents admit that he was never very bright. He is now almost blind. His blindness and ataxia seem to indicate a tumor of the pons, with some pressure on the cerebellum.

DR. WOLFE gave the results of the examination of the eyes in this latter (the boy's) case. There are choked discs on each side, and the external eye muscles are greatly interfered with, the abductors on both sides being especially affected. All movements of the eye are limited.

DR. WIENER said that in the first case the pathological condition present seemed to be a chronic internal hydrocephalus, an affection described some years ago by Quincke of Kiel in Germany. The presence of too much fluid in the ventricles of the brain in the cases causes pressure symptoms and atrophy of the optic nerves. The absence of any focal symptoms substantiates this diagnosis. The prognosis of the case is by no means absolutely fatal. Patients may often live for years. The best treatment is by inunctions of mercury. In a number of reported cases this has done good. In the second case, that of the boy, the involvement of both abducens muscles of the eye points to the fact that the tumor is very probably situated in the superior peduncle of the cerebellum. Its situation here would seem to be confirmed by the fact that the pupillary reflexes are perfectly normal. In this case a double trephining by relieving the pressure within the brain case might save whatever of sight is left, and such being indicated in the case, should certainly be undertaken. While in the first case lumbar puncture should be undertaken in order to relieve the pressure of the accumulated cerebrospinal fluid within the brain; in the second case lumbar puncture would not be advisable. The tumor is situated very close to the fourth ventricle, and any change of the pressure condition might lead to the exertion of some pressure upon the fourth ventricle and bring on a fatal termination.

DR. JACOBI said that he would certainly advise lumbar puncture to be tried in the first case; the operation was an extremely simple one, and could be performed without subjecting the patient to any risk.

DR. KOPLIK said that as a rule there was absolutely no danger in lumbar puncture, and it should be used more than it is at present, especially in such cases as the first one. Out of the thousands of cases in which lumbar puncture has been done up to the present time there seems to be only one case in which it has caused a fatal issue.

The first paper of the evening, entitled

A CASE OF SCURVY,

was read by DR. WALTER LESTER CARR. The paper, with the interesting discussion which it called forth, will appear later in the MEDICAL NEWS.

The subject of the evening was then taken up,

ANTIPYRESIS IN THE FEBRILE DISORDERS OF INFANCY AND CHILDHOOD.

The first paper on the subject was read by DR. ABRAHAM JACOBI, and was entitled

ANTIPYRETIC DRUGS, THEIR USE AND ABUSE IN THE TREATMENT OF FEVER.

Antipyresis may be obtained in many different ways. A direct method is the destruction of the microbes that cause the fever by the use of antiseptics. Then it may be secured by paralyzing the circulation, as by the use of veratrum viride or by digitalis. The effect of digitalis is, however, very unsatisfactory in this respect, and requires the use of more of the drug than is advisable. A lowering of temperature may be secured by acting upon the sources of heat production or by increasing heat elimination. Quinin acts upon the cells of the body and so prevents the production of as much heat as usual. There are drugs that produce a cutaneous hyperemia and free perspiration, and so lead to the elimination of heat. It has always been a question as to whether we could kill microbes once they had gained entrance to the blood and tissues of the patient by means of antiseptics. We can, but it is apt to kill the patient. We may paralyze their action, as Prudden did, by dilute carbolic acid. By methods of the same kind there is no doubt, despite all that has been said to the contrary, that we can make antisepsis effective in the cavities of the body.

Quinin acts upon the cells because it produces a fall of temperature even after section of the cord. Phenol acts upon the central and peripheral nervous system. Antipyretics of this kind undoubtedly produce good results. It has been objected, however, that high temperature is

Nature's conservative reaction by which she kills bacilli and forms antitoxins. Unfortunately fever kills cells also, and it would be absurd to talk of the beneficent effects, for instance, of heat in sunstroke. The mortality of fever is in almost exact proportion to the height of the temperature. Persistent high temperature kills of itself, while a remittent fever, though very high at intervals, does not. Fever depresses all cellular energy, and must be combatted.

There are, however, no ironclad rules in the matter. A temperature that is extremely harmful to one patient may have little effect on another. A disease may begin with high temperature and not exhibit any of it later. Whenever temperature is injurious it must be treated. To let high temperature quicken the breathing and heart action in pneumonia when so much depends on the activity of these functions, would be eminently foolish. Whenever high temperature threatens to produce convulsions the indication is to lower it. This is conceded by everyone. When there is a possibility of such a termination, or of any other serious symptom the same indication holds. Death has occurred from persistent high temperature even during convalescence from disease. Children stand high temperatures very badly. They are much more affected by any harmful influences than are older people, and the same holds true for small animals. Experimentally dogs two days old have starved to death in two days; at five years old they live for thirty days. The same thing has been demonstrated in pigeons.

It must be remembered that children are very different from adults in certain respects. They have less blood, for instance. A child's blood represents one-nineteenth of its body weight; an adult's one thirteenth of the body weight. There is less fibrin in their blood, and it is of less specific gravity. Hence the facility with which children become hydremic. Antipyretics cause rest, and so save the patient from harmful influences that would perhaps seriously affect the developing structures. Especially when water is indicated hydrotherapeutic measures will be found to give the child refreshing sleep. Antipyretic drugs give in a measure like results. Patients have idiosyncrasies, and then certain drugs must not be used. But after all it is not a Greek name for a disease, but a human being that is to be treated. Quinin is very effective wherever there is oscillation of temperature. It is a true antiperiodic as well as an antimalarial drug. For persistent high temperature it is not so effective. It may be given to children mixed with chocolate or in coffee syrup, and will be taken readily. In chronic malaria ergot has proved a very effective drug in my hands for nearly forty years. When first used it sometimes contracts the spleen and brings on an acute attack of malaria by throwing into the circulation malarial parasites that have been lodged in that organ. In such cases it is often well to combine it with quinin.

Salicylic acid is an effective antipyretic that acts centrally. It is very irritant, and so the sodium salt is preferable for administration. Oleum Gaultheria, which is practically methyl salicylate, is effective when applied externally in ointments. Antipyrin has been used a great deal abroad. The skin eruptions that it causes show that it produces changes in the walls of the blood-vessels. Certain patients have an idiosyncrasy against it. The drug seems to be inactive in brain disease. Salipyrin is an allied drug for which there is less idiosyncrasy. Acetanilid does not disturb the stomach and skin, but it should not be used because it is a poison to the tissues, and produces methemoglobin. Phenacetin resembles it, but is not so strong. Lactophenin sometimes produces jaundice. I have seen it once, and others report the same thing. When patients are weak, alcohol, by acting as a stimulant and dilating the peripheral vessels, causes a fall of temperature. This substance has been much abused, but still it should not be utterly condemned. It is too much to say, as has been said, that practitioners give alcohol just in proportion to their ignorance. In the infectious fevers I consider alcohol of the greatest possible service. In septic cases with high fever where 100 cubic centimeters of alcohol does no good, 200 to 300 may do good. I have seen 500 cubic centimeters, that is, 2 pints, taken with advantage in the twenty-four hours. As soon as the febrile stage is passed the alcohol causes delirium. It should not be given in the early stages of such diseases as pneumonia in which hyperexcitation of the patient is the rule, while it is of great service later. In chronic diseases it very often replaces food, and should be used freely and persistently.

DR. SIMON BARUCH read a paper, entitled

HYDRIATRIC MEASURES IN THE MANAGEMENT OF THE FEBRILE DISORDERS OF INFANCY AND CHILDHOOD, WITH PRACTICAL DEMONSTRATIONS OF THE VARIOUS HYDRIATRIC PROCEDURES.

He said in brief that there are certain differences in the hydriatric treatment of the diseases of childhood and of those of adults which justify the reading of a special paper on this subject. In general, it must always be borne in mind that water is something more than an antipyretic, that it is a real and important therapeutic measure. It is the child that must be treated in every disease, and not the fever which the child may have. Our object is to assist Nature in her efforts to overcome the disease, and not to jugulate the disease. For the restlessness of fevers in children nothing is more efficient than cool bathing. The water need not be at first so cool as to shock the patient. If we begin with the water at ninety degrees, getting it cool to eighty or seventy-five degrees, and then three hours later begin with water at five degrees lower in temperature, we will gradually accustom the patient to the application of cold water without shock. The refreshing sleep which occurs so soon after a cool bath will quickly persuade the parents to abandon any prejudices that they may have had against the bathing treatment. It is to be remembered that the vessels of the skin are capable of holding two-thirds of all the blood of the body. When they are distended because of the weakness due to fever, an excellent opportunity is given for bringing the temperature down readily and easily. But something more than reduction of temperature is accomplished by the use of the bath. It is the best possible stimulant to the nerves and to the

vascular system. This stimulation causes increase of function by the tonic effect it produces, and this, rather than antipyresis, is the main object of hydrotherapy.

In the use of hydrotherapeutic measures some almost incredible mistakes are made. I remember once being called in consultation by a physician who had a case of scarlet fever with a temperature of 106°F. which he was not able to bring down by means of cold baths. I found when I got to see the patient that he had been given but one bath, and that without friction. Shock had ensued, and the parents had very naturally objected to any further bathing. But by beginning with water that was not very cool, with carefully rubbing the child while it was in the bath, I succeeded in bringing the temperature down without much difficulty. Shock need not be feared in these cases. The rubbing should not be done with a sponge, as is so often the case, but with a rather coarse cloth that holds plenty of water. There are certain diseases that do not stand hydrotherapy very well. Pneumonia and scarlet fever are the most important among them, but with care proper measures can be adapted for the treatment of even these diseases with excellent results. Some of the best authorities have expressed in no uncertain tones their approval of hydrotherapy in children's diseases, among them I may mention Jacobi, Baginsky, Hutenel, Furbringer, Guimon, Jurgenson.

Dr. Baruch then demonstrated the method of applying the various compresses and packs that are used in hydrotherapy. He insisted especially that the wet compresses should not be covered with oiled silk, for the heat of the patient would very soon make poultices of them. A compress should always be covered with a piece of flannel or some other woolen material that permits of slow evaporation. The various packs should be wrapped closely around the body and the woolen covering above that should also be wrapped closely so as to permit the circulation of as little air as possible between the wet cloths and the body.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 19, 1899.

The President Dr. William H. Thompson in the Chair.

The paper of the evening read by Dr. Charles L. Dana, was entitled

LOCOMOTOR ATAXIA; ITS PATHOLOGY, PATHOGENY, IMPORTANT SYMPTOMS AND TREATMENT.

Dr. Dana said that he did not hope to say much that was new on so old a subject as locomotor ataxia, but wished to give a review of its present position in the light of his own clinical experience. It is essentially a nervous disease with changes due properly to the disease only in the nervous system. All other changes in the body are but secondary. The peripheral sensory neuron is the main seat of the disease. It is not essentially a disease of the spinal cord but rather of the spinal ganglion and its central branch, though the peripheral branch is also affected.

The functions performed by different sets of nerves in the sensory columns, true sensation, the muscular sense, pain, the temperature sense, etc., are developed at different periods in the growing organism. They are evidently carried by different sets of nerve-fibers. Tabes picks out these sets of fibers for its attack in varying ways and at different times in different individuals. In some cases the prominent symptom is ataxia, in others the absence of reflexes, in still others visceral or rectal sensory crises, or optic atrophy.

The disease attacks different segments of the cord in different cases. In some the lumbar segment is mainly affected, producing symptoms in the lower limbs, in others the dorsal segments are involved producing abdominal symptoms. At times the cervical enlargement is affected when we have the symptoms of superior tabes mainly affecting the arms and hands. At times the affection strikes even higher up, affecting first the nerves to the eye, which are homologous in large measure with the spinal nerves. At times even the motor roots are affected as the ocular palsies denote. At times the cerebral ganglion cells are affected, giving a set of cerebral symptoms that correspond in certain ways to the spinal ones. For the delusions of grandeur of general paralysis correspond very closely to the hyperesthesia and neuralgic crises which occur in the distribution of the spinal nerves.

We are practically agreed now that locomotor ataxia is always luetic, that is, if there were no syphilis there would be no tabes. It is not syphilis, primary, or secondary, or tertiary, but practically a history of preceding syphilis is present. The disease may not always be the lues of the syphilographer. Within the last few months, I have had a patient who having developed a primary sore was treated very carefully for syphilis by all the approved methods, including a series of hot baths at Hot Springs. He never had any other symptoms of syphilis except the primary sore. Yet ten years afterward he developed tabes. I have had a patient who, noticing a slight abrasion after suspicious intercourse, went to Agnew in Philadelphia. The symptoms were so slight, Agnew absolutely refused to treat him. For five months he insisted on calling on Agnew with regard to the matter. Agnew absolutely insisted that he had no syphilis. Yet later he developed tabes. How different all this is from typical lues. It would almost seem that there was another poison introduced at the same time with the syphilitic virus that produced the disease, or that there was some by-product of the syphilitic process. Certainly, there is something in the process that syphilographers do not ordinarily describe.

Two important factors in the etiology of tabes are heredity and overexertion. By heredity I mean not that there is a distinct history of transmission of family nervous disease, but that there is a neuropathic tendency. The basis on which tabes, like its cousin, hereditary ataxia, develops is a congenitally weak set of sensory neurons. It is, as it were, a teratological defect of the spinal nervous system. As to overexertion, tabes occurs particularly in people who are very much on their feet, as in salesmen, commercial travelers, soldiers and the like. It occurs in sailors almost never. The reason for their escape being seem-

ingly the perfectly healthy circumstances under which they live as regards fresh air. Overwork and alcohol do not seem to me to count for much in the etiology of the disease, and exposure to cold, despite the number of authorities who unite in describing it as a causal factor, has never seemed to me to enter very actively into the etiology of the disease.

With regard to symptoms, the two classical symptoms are the Argyll-Robertson pupil and the loss of the kneejerk. The pupillary symptom is almost sufficient by itself to justify the diagnosis of tabes. The loss of the kneejerk with one other symptom is sufficient for the diagnosis. In order not to miss the disease it is important to remember that about ten per cent. of the cases begin anomalously. A number of patients in my practice have presented rectal hyperesthesia as the first symptom. It was usually supposed that they were suffering from fissures, or piles or the like. Surgical intervention even sometimes gave relief. In some cases at first no other symptom could be found. Sometimes the pupillary reflex or the kneejerk, made the diagnosis.

Tabes often develops with its first symptom as a bad neuralgia. This may occur without defect of the kneejerk or any pupillary symptom or ataxia. Often the diagnosis must be made on the pain alone. The peculiar lancinating character and the perfectly good health of the patient in the interval are the characteristic signs. At times when no other symptom is present there is a slight swaying of the patient when asked to stand with closed eyes. In healthy persons the swaying is usually anteroposteriorly. Tabetic patients have a lateral sway. A very good test of the muscular sense is to have the patient stand on the toes with the eyes closed. Often when no other symptoms are present there are patches of anesthesia on the thighs or in the genital region. Gastric crises are frequently a solitary symptom, and are often treated as indigestion for long periods. In one such case I found a girdle of anesthesia at the level of the umbilicus which confirmed the diagnosis of tabes.

Sometimes the first symptom is a sudden causeless swelling of the knee or the ankle-joint, or the swelling may occur after very slight injury. Sudden fracture of a long bone without very much cause is always suspicious. If the patient has any history of previous syphilis, the case is more than suspicious of tabes. Laryngeal crises may occur early, but I have seen them very rarely. Patients describe a tickling sensation in their throats, a feeling of suffocation with intense dyspnea, or they may even have an epileptic convulsion as the consequence of these feelings.

Treatment.—The canonical treatment is first to give a rigorous anti-syphilitic course for six to eight weeks to be followed by tonic treatment, these to be repeated once a year or oftener. In the intervals small doses of mercury and the iodids are to be administered. Antisyphilitic treatment is perhaps supposed to do good because tabes is milder now than it used to be. Perhaps the justification for its administration is found in the fact that tabes is always a post-syphilitic disease. No neurologist can say definitely that syphilitic treatment does good, yet we somehow are persuaded that it benefits certain patients. Some neurologists even feel that we can not refuse to give antisyphilitic treatment though there be no syphilis in the history. It is time to change our opinions in this matter. If there is a history of syphilis then antisyphilitic treatment is indicated. The best method of administering mercury in these cases is by hypodermic injection of $\frac{1}{30}$ to $\frac{1}{20}$ of corrosive sublimate once a day in 30 minims of water. This should be continued for from two to four weeks, according to the susceptibility of the patient. Then, potassium iodid should be given, beginning with 30-grain doses three times a day and increasing the dose but not to more than 330 grains per day. This is continued for four weeks and then an interval of six to eight weeks is allowed to elapse. If the patient does not stand hypodermics of mercuric chlorid well then inunctions should be given. These may be continued for six days, the patient then should take a bath, and continue the inunctions then for six days more, and thus persist in the treatment for four or five weeks, or until symptoms of mercurial saturation come on. Tonics should be used, especially phosphorus. Lukewarm baths from 94° to 96° F. are of a great deal of service. They may be given with or without a cool affusion at the end. These baths may contain some salt, or even the carbon dioxid baths may be used, and are often of service.

During the tonic period of treatment counterirritants may be applied to the spine. Patients should rest a good deal, should go to bed early, sleep late and take an hour's sleep in the afternoon. They should be much in the open air, they should take exercise by riding, not walking. Neither an excessive meat diet nor one consisting of vegetables only is good, but a judicious mixture of both. Patients suffer enough without depriving them of all consolation, so that if they use tobacco and alcohol in moderation these may be permitted. It is better to leave them at their business so as to furnish them an occupation for their mind and not forbid them amusements. The tonic and bath treatment should be repeated at least once a year.

When there is absolutely no syphilitic history then antisyphilitic treatment should not be given. There is no evidence of its ever doing any good and if the patient is delicate it may do harm. Tabes is practically a premature senility of the sensory neurons. The best thing at the beginning of treatment then is a two months' rest and bath treatment. The best specific for the disease is an absolutely regular life such as is followed in hospitals. While the poor get better in hospitals, the rich often experience no improvement at home. Institutional treatment is a real specific. Electrotherapy is also of service. Nitrate of silver, while of course not the specific that it was formerly claimed to be, sometimes does good. It should be given in quarter-of-a-grain doses three times a day. The combination of strychnin and morphin has been effective in my hands. Patients should usually be put to bed, while the strychnin is being administered. I give $\frac{1}{60}$ of a grain of strychnin and of morphin, and gradually increase the dose to $\frac{1}{30}$ of each at the end of a week and to $\frac{1}{20}$ at the end of three weeks. I rarely give more than this, though at times I have given as much as $\frac{1}{5}$

three times a day. I always diminish the dose gradually before leaving off its administration. I repeat the process after three months. It must be borne in mind that strychnine may increase the pains, and may even cause collapse, when of course it is contraindicated. It should not be given in very acute cases and it should not be given in absolutely stationary cases, nor in incipient cases.

While hot baths may be dangerous, lukewarm baths especially with a cold affusion are very serviceable. They would better be taken at home than at thermal springs. Patients meet others suffering from the disease at watering-places and learn too much about the affection for their own good. Some months spent at a hot spring often do good, notwithstanding, and there are springs here in America and in France as well as at Nauheim in which patients are distinctly improved.

Stretching of the cord has been practised. Patients should sit on a board, while the head is bent forward between the legs and this position maintained for eight or ten minutes. In some cases this relieves the pain, restores the sexual potency, and benefits the ataxia, so that it should be tried. With the Fraenkel treatment I have been rather disappointed. It is supposed to train the patients to walk again, but in most cases it seems to do very little good. Suggestion is an important feature in the therapeusis of tabes and must never be neglected. Patients must not be left to think that something can not be done for them. Assurance must be given them that time and patience will make their malady much more bearable and that an alleviation of their symptoms will be secured.

In the discussion Dr. G. M. Hammond said: Tabetic symptoms are not necessarily due to an essential disease of the neurons. The affection may be a sclerosis, the overgrowth of connective tissue causing a secondary degeneration of the nervous element. The pathological change may be a syphilitic occlusion of the blood-vessels of the cord, thus depriving the nervous elements of their nutrition and thus cause them to degenerate. Antisyphilitic treatment is indicated. It does not improve the condition, but it prevents further changes. Moderate exercise constantly taken is the best for tabetic patients. Electricity of any kind never does any good. Hydrotherapy is of service, but drugs in the water are not of value. The skin does not absorb medicaments. Fraenkel's method of reteaching co-ordination has not been as beneficial in my experience as I expected. It is doubtful if it does more than teach patients to use their muscles under the direction of their eyes.

Dr. Joseph Collins said: Tabes is not a disease of the spinal cord. The sooner we get rid of this idea the better. It is a disease of the peripheral sensory neurons, part of which happen to extend into the cord. I have no patience with those who still hold the theory that syphilitic vascular changes have anything to do with the degeneration of the nervous elements. No such vascular changes have ever been observed post-mortem in simple tabetic cases. I do not agree with Dr. Dana as to the neuropathic condition of patients in whom tabes develops. In one hundred cases that I have examined very carefully for this purpose I found no psychical or somatic stigmata of a nervous disposition. The trouble is that we do not know how to treat syphilis. The syphilographers tell us that they can cure syphilis, but years after their pretended cure come the nervous troubles that the neurologists see. I have no faith in antisyphilitic treatment for tabes itself. In cases where there is no syphilitic history I would as soon think of giving diphtheria antitoxin as of giving mercury, in fact much rather, for there might be some hope that it would act in opposition to the toxin in the system. We do patients harm, we put out their eyes, we hasten the development of ataxia symptoms by the depressing effect of mercurials. Tabes is not milder than it was. It is only that we see milder cases now that our diagnostic methods enable us to recognize its minor forms. Institutional treatment is the ideal. Even the poor patients on the islands here in New York get along much better than the rich patients for whom so much is done at our offices and at their homes.

The Fraenkel treatment has given excellent satisfaction in my hands. Some years ago a dancer became famous by appearing at a private dinner. A year later she came to my office practically helpless from locomotor ataxia. After treatment by the Fraenkel method she is now playing one night stands all over the country making her living once more as a dancer. Electricity is not curative, but it stimulates and encourages the patient and does good by suggestion.

Dr. Sachs said that it must not be forgotten that the most noticeable lesion of tabes found post-mortem is the degenerative process in the cord. To remove the disease from the realm of spinal diseases would be a mistake. With regard to the treatment of tabes it must be borne in mind that there is often in the disease an element of active though not patent syphilis. In all such cases antisyphilitic treatment is of distinct benefit. Such cases are more frequent than is thought. Under this treatment the knee-jerks sometimes return and even the ataxia and other characteristic symptoms of tabes improve. Such improvement has been observed especially by Erb. Of course it is well understood that the disease that is helped by the mercury in these cases is really cerebrospinal syphilis.

Rest is a very good remedy for tabetics. In many cases the putting of the patients to bed for from three to four weeks will benefit them so much as to amply repay them even in their own estimation for the enforced idleness. Dr. Dana seems to underrate the value of the Fraenkel method of treatment for the incoordination for tabes. In my experience almost all the patients on whom it has been faithfully tried have been distinctly improved. Patients do not care whether the pathological condition on which their disease depends is modified or not, provided their symptoms are relieved. This is exactly what is accomplished by the Fraenkel training, for it enables them once more to control their movements.

Dr. M. Allen Starr said that we are prone to accept exaggerated opinions in medicine. It seems too much to say that the disappearance of syphilis would mean the disappearance of tabes also. Only Moebius in

Germany now claims that tabes is due to syphilis alone and in every case. Even Erb has been able to find syphilis in only a little more than 89 per cent. of his cases. Personally I have found no reason to think that syphilis had existed previously in about 40 per cent. of my cases in private practice. Most of the patients were thoroughly reliable and intelligent, their confidence had been completely won and there was no reason left to think of deception on their part. Syphilis is undoubtedly of great importance in the etiology of tabes, but there are also other causes.

As to antisyphilitic treatment for tabes, it would seem to be entirely justified only when there is syphilis in the patient's history and some symptoms of active syphilis present. In Japan while syphilis is very common tabes is very rare. These facts I have on the most trustworthy Japanese authority. The most plausible reason for this escape of the Japanese from tabes would seem to be due to the fact that they bathe so freely. The peripheral nervous stimulation so frequently recurring tones up the central nervous system and enables it to withstand better the ravages of disease. Hydrotherapy should then be of the greatest service in the disease. Strychnin, however, has always in my experience increased the pain and I no longer use it.

DR. WILLIAM H. THOMSON said that the greatest source of errors of diagnosis in the initial stages of tabes is the occurrence of visceral symptoms. Gastric symptoms are especially liable to misinterpretation. Not long ago in a case that had been treated for a long while as dyspepsia, the only symptom was recurring attacks of excessively painful flatulence. The suspicious circumstance in these cases is the absolute freedom from symptoms in the interval. For the peripheral anesthesias and paresthesias, red pepper locally is of benefit. For the pains, acetanilid is very useful, especially combined with belladonna. Patients improve very much on cod liver oil. Artificial Nauheim baths, that is carbonic acid baths, do good. The rest cure is efficient but expensive. Patients come to us in order to enable them to stay at their work. When rapidity of pulse develops, the general condition will always be improved by the use of intestinal antiseptics. Tachycardia developing in the midst of any disease will usually be benefited by the same method of treatment.

REVIEWS.

ON THE STUDY OF THE HAND FOR INDICATION OF LOCAL AND GENERAL DISEASE. By EDWARD BLAKE, M.D., Member of the Royal College of Surgeons. Second Edition. New York: G. P. Putnam's Sons, 1899.

THE fact that a second edition of this little work should be called for proves one thing certainly: that the profession is still mightily interested in all things, even in special details, which go to aid in establishing a diagnosis. The author has added several new chapters to this edition, including a discussion, as to the causation of chloroform syncope. This is considered in the relation of respiration to the pulse. The tremors are also fully treated of, and some new plates have been added to illustrate the conditions described. A book like this makes for accuracy in diagnosis and as such it has a value distinctly its own; but we think the author has been a little over-zealous perhaps in finding more in the hand than disease actually presents, or, better, that his observations have been tinctured with prejudice. Be this as it may, the book is very interesting and should commend itself to a large audience.

THE DISEASES OF THE NERVOUS SYSTEM. A Textbook for Physicians and Students. By DR. LUDWIG HIRT, Professor at the University of Breslau. Translated, with permission of the author, by AUGUST HOCH, M.D., formerly Assistant Physician to the Johns Hopkins Hospital, now to the McLean Hospital, Waverly, Mass., assisted by FRANK R. SMITH, A.M. (Cantab.), M.D., Instructor in Medicine in the Johns Hopkins University, with an Introduction by WILLIAM OSLER, M.D., F.R.C.P., F.R.S., Professor of Medicine in the Johns Hopkins University, etc.. New York: D. Appleton and Company, 1899.

AFTER reading this work, one cannot fail to be impressed by the vast clinical experience of the author. It teems with original observations throughout and shows thorough familiarity with nervous diseases. However, nearly six years have elapsed since Hirt penned the introductory lines to the second German edition—of which the book before us is a translation, and during this time much has been written upon the subject of which no mention has been made. This is particularly noticeable in the discussion of myxedema and acromegaly, both subjects being dealt with in far too cursory a manner.

Following each subject is a list of the literature, arranged in a chronological order, ending with the year 1894. This, as far as it goes, enhances the value of the book as a work of reference. As a text-book for students we cannot commend it; as a reference work it has its place.

The book contains a large number of woodcuts, some of which are ludicrously crude in these days of superbly illustrated medical works. They are, however, for the most part, satisfactory, and add materially to the value of the book.

REPORT ON THE INVESTIGATIONS INTO THE PURIFICATION OF THE OHIO RIVER WATER FOR THE IMPROVED WATER-SUPPLY OF THE CITY OF CINCINNATI, O. Made by the Board of Trustees, Commissioners of Water Works. Cincinnati Commercial Gazette, Job Print, 1899.

THE volume before us is another one of a series of exhaustive reports upon the question of improved water supply for large cities. The investigations carried on at Cincinnati are similar to those carried on at Louisville the report of which was reviewed in these columns some months ago. At Cincinnati, Ohio River water is consumed and the source of the two cities being practi-

cally the same, we would naturally expect the same treatment, which, in short, consists of a modification of the English system. In this special case subsidence, addition of coagulant (sulphate of aluminium), and further subsidence before filtration through American "mechanical" filters is the method practised. We find the relative cost of the method here described to be about 3.8 per cent. cheaper than the improved English method. We are pleased to note that the new intake is above the discharge center of "thirty-two small sewers and drains," below which the old intake was situated. The book is clearly written, and is embellished by many plates of the experimental plant and other structural matter, all of which are drawn to scale.

INTERNATIONAL CLINICS. A quarterly of clinical lectures on Medicine, Surgery, etc., and specially prepared articles on Treatment and Drugs by Professors and Lecturers in the leading Medical Colleges. Edited by JUDSON DALAND, M.D. Volume III. October, 1899. Philadelphia: J. B. Lippincott Company.

THE feature of this issue of the International Clinics is the series of articles on Treatment. While American medical men generally will not agree with Professor Stintzing of Jena, as to the treatment of incipient appendicitis, it, at least, is interesting to find that he has the courage of his convictions in the matter of treating appendicitis with opiates. For instance, he says, "our patient is under the opiate treatment, which is, as you know, we consider, the only rational internal treatment under the circumstances. He has not had a stool before in eleven days and we have not considered it necessary to give him a purgative or take any means to secure an evacuation, as we felt sure that nature herself would take the best and most natural method to clear the fecal matter from a practically normal large intestine as soon as we had ceased quieting peristaltic movement by opiates.

Professor Grancher of Paris, the well known specialist on tuberculosis, presents the third of a series of clinics on the treatment of tuberculosis. Professor Ernest Kuester of the University of Marburg has a very interesting clinic on the surgical treatment of tuberculous nephritis, in which he suggests the examination of the other kidney by an exploratory incision whenever it has been decided to remove a tuberculous kidney.

Professor Helferich of the University of Griefswald, who lately accepted Professor Esmarch's chair as professor of surgery at the University of Kiel, reviews the treatment of recent and old fractures of the patella. What is novel in the clinic is the suggestion, original with Professor Helferich himself, that in old cases of fracture of the patella where the fragments are widely separated and contracture of the quadriceps is too great to allow of the hope of bringing the fragments together, pieces of sterilized bone should be inserted in the gap, between the fractured ends. This makes an unshapely patella, in certain respects, but as no two patellas are very much alike it is not noticeable, while the pully function of the quadriceps over the knee-joint is restored.

Dr. A. Goldscheider of Berlin, presents a most practical review of the treatment of tabes dorsalis. The Fraenkel treatment of tabes, by training the patients until they regain their coordination, is given with special detail. Certain features introduced into this system of treatment by Professor Goldscheider himself are of particular interest. Exercise for hemiplegics while in the bath is a very practical bit of treatment which Dr. Goldscheider introduces into the clinic in passing.

Professor Gerhart of Berlin has a very interesting contribution on apoplexy during pregnancy. Professor Gerhart does not believe, as most of the French school do, that the heart is hypertrophied during pregnancy; nor does he believe that there is any essential reason in pregnancy itself why apoplexy should occur more frequently at this time than at any other. Its occurrence is due always to secondary factors.

A note on epicondylalgia, that is the pain which occurs in the group of muscles attached to the epicondyle by Professor Bernhardt of Berlin should prove very timely just now. The functional neurosis called by this long name is due to certain strains on the forearm, such as occurs in delicate persons from holding up an umbrella, or in these modern days may come from holding up a heavy set of skirts.

THERAPEUTIC HINTS.

For Acute Pharyngitis.—

1. ℞ Potassi chlorat. . . . gr. xv
   Ol. menth. piper . . . gtt. ii
   Ext. krameriæ . . . gr. xv
   Ext. glycyrrh. . . . ʒ iiss.

M. Ft. troch. No. xxx. Sig. One troche every two hours.

2. ℞ Ammonii chlor. . . . gr. xxx
   Pulv. ipecac. . . . gr. ii
   Pulv. capsici . . . gr. ½
   Ext. glycyrrh. . . . ʒ ii.

M. Ft. troch. No. xx. Sig. One troche every two hours.—*Lefferts.*

For Prolonged Attack of Hiccoughs —

℞ Strychninæ sulphat. . . . gr. $\frac{1}{40}$
Camph. monobrom. . . . gr. ½
Hyoscyaminæ . . . . gr. $\frac{1}{50}$.

Sig. For one dose. Repeat according to indications.

Medication in Gastric Dilatation.—

1. ℞ Bismuthi salicyl.
   Magnesiæ
   Sodii bicarb. } aa. . . ʒ iiss

M. Div. in chart. No. xxx. Sig. One powder after each meal.

2. ℞ Bismuthi salicyl.
   Salol
   Magnesiæ } aa. . . ʒ iiss

M. As above.

3. If diarrhea be present:

   ℞ Bismuthi salicyl.
   Salol } aa. . . ʒ iiss

M. As above. *Dujardin-Beaumetz.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXV. NEW YORK, SATURDAY, DECEMBER 9, 1899. NO. 24.

ORIGINAL ARTICLES.

THE BACTERIOLOGY OF YELLOW FEVER ONCE MORE.

(Translated.)

BY PROFESSOR G. SANARELLI,
OF BOLOGNA, ITALY:
PROFESSOR OF HYGIENE AND DIRECTOR OF THE INSTITUTE OF HYGIENE AT THE ROYAL UNIVERSITY OF BOLOGNA.

THE latest phase of the scientific discussion concerning the causative agent in yellow fever has led us into a path which threatens to last forever. The question at issue is becoming more and more involved, and is being practically lost sight of in the present discussion by many bacteriologists. It seems to me that the recent publication of the Report of the Commission of Medical Officers,[1] detailed by authority of the President of the United States to investigate the cause of yellow fever in Cuba ought to put an end to further controversy. This report, drawn up in the most conscientious manner, definitely substantiates the etiologic value of the bacillus icteroides. There are certain points of interpretation, it is true, though of very secondary importance, with reference to which there still exist some slight differences of opinion between the results of my own investigation and those of that commission. But these do not affect in the slightest degree the fundamental question at issue.

The investigations of the commission, with regard to yellow fever, I may say in passing, have been conducted with such evident seriousness, thorough preparation and scientific exactness that they form a striking contrast to the almost incredible and unpardonable levity with which a number of my opponents have thought it not improper to approach so important and so difficult a question.

It is perfectly true, as Dr. Novy[2] said, in his last article in reply to me that every scientific publication is open to doubt and should be submitted to scientific criticism. But it is also very true that criticism should not go beyond certain limits established by custom and that the discussion should always maintain a high scientific character, otherwise it will not be possible ever satisfactorily to determine a question. After having sustained with an unreasoning obstinacy that is only equalled by the ill success of their efforts the identity of the bacillus icteroides with that of Dr. Sternberg's bacillus X, Dr. Sternberg,[3] and his disciples, Drs. Reed and Carroll,[4] now dispute my discovery from other and entirely different points of view. So much has been said in fact, that in order to defend myself and satisfy every one, I should have to write an article every day, and there would never be an end of the controversy.

As a matter of fact, the arguments advanced by my eminent adversary, when seriously examined, frequently seem either without foundation or paradoxical; while the continuous insistence with which they are brought forward on every possible occasion renders response to them somewhat embarrassing. I am indeed somewhat of the conviction that the whole discussion is a miserable waste of time, and can have no definite scientific importance.

In this, my last paper in the discussion, I shall ignore entirely all the unimportant collateral questions, and shall set forth the arguments for my position as to the specific pathogeneity of the bacillus icteroides in its simplest and clearest terms. I have proclaimed and still proclaim that the bacillis icteroides is the specific causative agent in the etiology of yellow fever. Before my investigations, it had not been isolated nor recognized by any bacteriologist, nor had it been discovered in any malady, and it had never been found in a human cadaver. Since the publication of my investigation it has been isolated by Mendoza,[5] and Ramos[6] in Brazil; by Mesa-Gutierrez and Orvieto[7] in Mexico; by Pothier[8], Archinard and Woodson[9] in New Orleans; by Agramonte[10] in Cuba; by Wasdin and Geddings[11] in Louisiana, in Mississippi, and at Havana, and finally by Gauthier[12] in a case of yellow fever transported to Marseilles from Brazil on the steamer "Provence."

It may therefore be set down as definitely decided: *First, that the bacillus icteroides is undoubtedly found in patients who are ill of yellow fever, and in cadavers of those who have died from the disease.* This is not an opinion. It is a fact.

[11] "Report of Commission," etc., *ut supra.*
[12] *Revue d'hygiene*, October, 1898.

My first investigations, carried out in the only way that was possible under the circumstances, without any guidance from the labors of others, in the midst of manifold inconveniences and in laboratories improvised from day to day on my journeys, allowed me to isolate the bacillus icteroides in only a little more than half the cases. I made this declaration with perfect sincerity at the time, just as Loeffler in his first communication in 1884 with regard to the discovery of the bacillus of diphtheria confessed that he had not been able to isolate this micro organism in every case from the throat of diphtheritic patients. The final demonstration of the specificity of the Loeffler bacillus was made only four years later in 1888, when Roux and Yersin were able to demonstrate in animals the specific lesions of the disease, analogous to those which occur in human diphtheria. I was able to definitely demonstrate the specificity of the bacillus icteroides not only as the result of a very large series of comparative observations in animals, but also after having performed a series of decisive experiments on human beings.

I can not ask that this last series of observations be repeated, but I must demand that they should be believed, and I can not permit them to be discussed lightly since I have seen the results recorded with my own eyes, and my observations were confirmed at the time by a number of colleagues who were as familiar as I was myself with yellow fever. When I declare that by means of the toxin of the bacillus icteroides I can reproduce in man the typical picture of yellow fever, I must ask that I shall not be met with the obvious objection that others have been able to obtain the same results by means of other microbic toxins. I am perfectly familiar with the investigations made in this matter by Fraenkel[1] and Rumpf.[2] They produced certain symptoms in man by injections of the toxin of typhoid fever and of the bacillus pyocyaneus, but these authors have never reproduced either yellow fever or its symptoms, nor its anatomical lesions. If I had not been able to reproduce in man genuine yellow fever, I would never have been justified in declaring categorically that I had discovered the specific cause of the disease. I would practically have lost none of the prestige of my discovery had I simply announced the bacillus icteroides as a probable cause of yellow fever, leaving to others the duty of establishing this fact definitively.

The typhoid bacillus to which Eberth's name is usually given was not isolated by Eberth, but by Gaffky. Eberth had simply the distinction of having seen it first, and this of itself alone suffices to establish the priority of a discovery. After all it must be remembered that I was not a novice in the field of bacteriology, nor was I making my first discoveries, and it would have been difficult to persuade me to compromise my reputation as a bacteriologist by the imprudent affirmation of facts that could not be substantiated. But even prescinding from such considerations, which, after all, are of secondary importance, it has come about that when investigations could be made with ample assistance and with every convenience of time and deliberation necessary for such work, the bacillus icteroides has been isolated in every case of yellow fever.

In fact, Archinard and Woodson in Louisiana[1] isolated the bacillus icteroides in eighty per cent. of their cases. Wasdin and Geddings[2] after their lengthy mission of investigation in Louisiana, in Mississippi, and in Cuba declare that the bacillus icteroides can be found in practically every case of yellow fever. The other writers whom I have mentioned above, though they have obtained the bacillus icteroides from yellow-fever patients and from the bodies of such patients after death, have not taken the trouble to calculate the percentage of cases in which it could be isolated. Agramonte,[3] who was sent by Dr. Sternberg to Havana to make control tests of my investigations, alone, protested vigorously that he was able to isolate it only five times in eleven cases. But he himself confesses that he was not able to carry on his investigations as completely as he would like to have done, because of limited supply of laboratory appliances, and because of the arduous and exhausting work which he had to carry on as a member of the medical staff. This confession accounts amply enough, it seems to me, for his partial success in the investigation. Under such arduous conditions of observation no one could hope to secure better results than did Agramonte under the circumstances.

We may set down as a second conclusion then, *that the bacillus icteroides can be isolated from practically every case of yellow fever.*

In spite of the repeated substantiation of my investigations Dr. Sternberg and my other opponents have raised the doubt that the bacillus icteroides may be nothing more than a very commonplace micro-organism present as a secondary infection. As to this I may be permitted a few brief considerations. How can it be conceded even *a priori* that a microbe which is found constantly in patients sick with yellow fever and in the bodies of those who

have died from the disease; which can be isolated during the life of the patient and which constantly produces a perfect specific serum reaction with serum taken from the bodies of yellow-fever patients, from those actually sick of the disease, from convalescents, and from those who have recovered for many years from an attack of yellow fever; which reproduces in animals and in man, by itself and also by means of the toxins elaborated from it in vitro, the symptoms and characteristic lesions of yellow fever, can ever be considered as a simple microbic intruder on a par with all the other micro-organisms of secondary infection, which are well known and have been studied experimentally in every part of the world, because they are practically the same everywhere and in every disease. Besides this we know that careful observation demonstrates that the bacillus icteroides is the only microbe constantly present in yellow fever.

Archinard and Woodson in New Orleans have succeeded in obtaining agglutination in cases of yellow fever in ninety-three per cent. of the cases under observation. I was not able to obtain it in a single instance in eighty-six cases of normal blood, or in patients sick with other diseases than yellow fever, and have never succeeded in obtaining it in a single case in which the patient was either not actually sick with yellow fever or had suffered from it years before. Wasdin and Geddings during their mission in Havana studied carefully the bodies of thirty-one individuals who died from the most diverse maladies known and unknown, but all different from yellow fever and did not succeed in finding in a single case the bacillus icteroides present.

There has been but one discordant voice in the midst of the perfect unanimity in this matter, and that as might have been perhaps, foreseen, belongs to Dr. Agramonte, who was sent to Havana by Dr Sternberg. I have never attached much importance to Dr. Agramonte's work for the reason given above, but Drs. Reed and Carroll refer to it very confidently and seem to consider it of the highest importance. It will be well for us then to see how things stand in the matter. Dr. Agramonte sent a report to Dr. Sternberg from Havana, which was published during the current year.[1] He describes the case of a soldier who died with suspicious symptoms as he himself says, "a disputed case." At the autopsy he succeeded in isolating, first the bacillus icteroides, second the colon bacillus, and third, a form of typhoid bacillus. Very naturally Dr. Agramonte takes advantage of so promising an opportunity and immediately assumes that this supposed typhoid bacillus was the prime factor in the soldier's illness. He finds a way to make it appear that the patient really died of typhoid fever complicated by a secondary infection with the bacillus icteroides. In order to give more weight to his declaration he affirms that the other members of the yellow fever commission, especially Drs. Wasdin and Geddings, had arrived at the same conclusion. It does not require any hypercritical acumen, however, to decide that the disputed case was in reality a case of genuine yellow fever; and that the supposed bacillus of typhoid could be nothing else than one of the numerous bacilli belonging to the same family as the bacillus of Eberth, whose presence I have frequently demonstrated in the cadavers of patients dead from yellow fever[1] and which two of my students, Puppo and Ottoni[2], have already made the object of lengthy and detailed researches under my direction. Not only can this be presumed to have been the case but Wasdin and Geddings declared explicitly that the case of which so much account was made by Dr. Agramonte (Case No 7 of their report) was without doubt a case of genuine yellow fever.

Drs Reed and Carroll[3] were imprudent enough, notwithstanding all this, to announce that they had examined the liver of this case histologically and to announce that "from the microscopical findings we are strengthened in the belief that the bacillus icteroides in this case should be considered as a secondary invader" I can only think that in this they were joking at the expense of the suggestibility of their readers. As if they thought for a moment that it could be supposed possible to believe that by means of a microscopic examination they were able to make the bacteriological diagnosis of the bacillus icteroides in the midst of hepatic tissue, and then could afterward affirm that its invasion was primary or secondary. This assumption of theirs can only be the result of a too vivid imagination, and we can scarcely be expected to follow them seriously. From what I have said I think we can deduce the logical conclusion—*third, the bacillus icteroides is found only in those sick of yellow fever, or in the bodies of those dead from the disease. No one has ever succeeded up to this in finding it in a patient sick from any other disease; nor in the cadaver of any but an individual dead from yellow fever.*

We come now to the experiments on animals. As is the case with typhoid fever, with cholera, with infections by the pneumococcus, or the streptococcus, there exists no single lesion that can be said to be absolutely pathognomonic of yellow fever. The catarrhal lesions of the gastric and intestinal mucous

membranes, the erosions of the stomach, the hyperemia of the meninges, and of the parenchyma of certain organs, the hemorrhagic manifestations, the nephritis, the albuminuria and so forth, have, it is true, a particular importance in yellow fever, but they can be found in a great many other morbid conditions either as essential lesions or as secondary complications. Not even the fatty degeneration of the liver can be strictly said to be absolutely specific for yellow fever, since it is found at times in certain other morbid conditions. Despite all this the lesions of yellow fever when taken altogether, as Jaccoud very well says, constitute a pathological criterion that is more complete and more definite for this disease, than the pathological picture presented by the majority of the infectious diseases.

Now as it is impossible to reproduce the clinical picture of yellow fever in rabbits or guinea-pigs, or in animals generally, because yellow fever, like typhoid fever, cholera, pneumonia, and so forth, is essentially a disease that is limited to human beings, the question of the experimental study of the disease in animals must limit itself to the investigation of the question whether the micro-organism, which is supposed to be the specific causative agent of yellow fever, is capable of producing more or less completely all the principal symptoms and the lesions which are considered as more or less characteristic of the disease. As a matter of fact, we are able to obtain in animals, and especially in dogs, practically the whole anatomical and symptomatological picture of the disease. The modern scientific literature of the characteristics of the bacillus icteroides is unanimous in supporting this declaration. There is especially one lesion, however, which can be considered as of the very greatest value and as of almost pathognomonic importance in the post-mortem recognition of yellow fever in human beings. This is the extreme fatty degeneration of the liver. I would like to make it clear at first that when I speak of fatty degeneration I do not attach to the term in the present instance any vague or generic signification, because it is very well known that in many other infectious diseases, human and experimental, the hepatic cell can be affected by degenerative processes, more or less profound. I wish to designate, as a specific fatty degeneration produced by the bacillus icteroides, the true steatosis of the liver: that is to say, a state of extremely profound fatty degeneration, which is produced acutely and with so much intensity that the liver is affected to such a degree, so far as we know up to the present time, by but two specific morbid processes, namely, phosphorus poisoning and yellow fever. I insist upon this point, because I think it can be shown that by this lesion alone the morbific agent that produces it can be distinguished from every other. Its extreme steatogenic power, with regard to all elements of the body in general, but especially with reference to the hepatic cell, distinguishes the bacillus icteroides from all other pathogenic agents.

This important phenomenon can be observed especially and very noticeably in dogs. Foa,[1] Della Rovere,[2] Belfanti[3] and Zenoni, Bruschettini,[4] Wasdin and Geddings[5] have also observed it in a very marked degree in rabbits, and while Bruschettini has seen it also in pigeons and in turtles.

In the dog, all the observers who have investigated the subject carefully with the necessary experimental ability and without preconceived prejudices, have succeeded in finding this pathogenic action of the bacillus icteroides. To deny it now would seem the veriest absurdity. It suffices to read the experiments of any of the investigators of the bacillus icteroides, of course with the exception of Drs. Sternberg, Reed, and Carroll, and Novy, to find a description of an intense steatosis which has always been obtained with the bacillus icteroides, and never with any other micro-organism. I must, of course, concede to my opponents that not all the races of dogs are possessed of hepatic elements which are equally sensitive to the toxin of the bacillus icteroides. The age of the animal, and especially the race to which it belongs, exercise undoubtedly an important influence in the modification of the phenomena. If the experiments are continued, however, the observer will always succeed in obtaining such examples of acute steatosis of the liver as cannot be obtained experimentally, even when the animals are poisoned by large quantities of phosphorus. The liver appears absolutely yellow. It is anemic, and its density is greatly increased. The picture which I have had drawn and reproduced in my monograph is the only thing that can give a proper idea of its appearance to those who have not actually seen it. It must be remembered that in cases which run a very acute course the dark yellow color characteristic of the fatty degeneration is masked by the congestion, which has been set up in the organ by the intense irritation of the toxins of the disease. It suffices, however, to produce a slight superficial ischemia, by simple compression with the finger, for instance, to produce an immediate return of the dirty yellow color, and this at once discloses the profound steatosis of the organ that has taken place.

[5] "Report of Commission of Medical Officers, sent out by the President of the United States, etc., Washington, 1899."

I have not myself seen, nor have any of the well-known investigators who have repeated and confirmed my experiments, ever observed anything similar to this important lesion in animals dead from any other microbic infection. This demonstrates that the steatosis, the true and complete steatosis, which transforms, as I have often seen, the whole liver into a compact mass of fatty degenerated material, is peculiar to the bacillus icteroides.

I have made a great many observations in this matter and the number of dogs that have been killed in my laboratory runs up into the hundreds. As a detail in my last article in the MEDICAL NEWS I have even carefully calculated by mechanical methods the amount of fatty material contained in the liver of dogs killed by the bacillus icteroides in order to compare it with that obtained from the livers of animals killed by other methods of experimental infection. Our experiments included microbes as varied as the cholera vibrio, the colon bacillus, the bacillus pyocyaneus, the bacillus of diphtheria, and the bacillus icteroides. The last mentioned bacillus was capable of producing in a shorter period of time a much larger quantity of fatty material than any of the others. I am myself almost convinced that in Dr. Sternberg's laboratory they have never succeeded in obtaining this steatosis, for it is so peculiarly characteristic that it would at once have attracted attention and convinced even the most skeptical of the specificity of the agents producing it because its appearance is not only extremely peculiar, but because it has an absolute analogy with the appearances which are so well known in human cadavers after yellow fever. This convinces me that perhaps in the Army Medical Museum experiments are devoid of value as far as regards yellow fever, because they are working with a bacillus which is not the bacillus icteroides. It is not possible to admit that in Washington the bacillus icteroides seems to be endowed with characteristics very different from those which have been found repeatedly and indisputably in other cities of the Union, and in all the other countries of the world.

The number of observers who have noted this characteristic steatogenic power of the bacillus icteroides is very large, and is well known by those who follow the literature of the etiology of yellow fever. It is evident then that the negative results obtained by Dr. Sternberg and by those working under his direction are deserving of very little confidence. I think we may without further ado draw the following conclusion: *Fourth, the bacillus icteroides reproduces in animals all the symptoms and all the anatomical lesions which can be considered especially characteristic of yellow fever in human beings.*

Having said this much I may be considered I think rigorously to have fulfilled my duty. Koch's famous laws may seem to have lost some of their primitive and absolute value in our day. Yet, notwithstanding this, it is true that the bacillus icteroides, considered as the specific causative agent of yellow fever, is in all important particulars perfectly in accord with these laws. First, it is found in practically every case of yellow fever. Second, it is never found outside of yellow fever. Third, it can be cultivated in artificial nutritive media. Fourth, it reproduces in animals an anatomical and symptomatic picture analogous to that of yellow fever in the human being.

I have still to reply, however, to certain objections which have been more or less courteously urged against the results of my investigations by Drs. Reed and Carroll. The insistence of these two young bacteriologists of the Army Medical Museum, it strikes me, is due rather to an unfortunate deference which they have for the opinions of their surgeon general than to any special desire for the advancement of scientific truth.

I certainly do not feel that it would be quite proper to force Drs Reed and Carroll into insubordination to what they seem to think their duty, nor do I wish to tire the reader's patience nor take up valuable space in the MEDICAL NEWS in discussing point by point their last article.[1] In that article, while professing a spirit of the greatest courtesy towards my modest person, they get into a most inextricable confusion of experimental results and scientific deductions, but somehow out of it all they emerge at the end with enough energy and self-confidence left to insist that the bacillus icteroides is identical with, or at least is a variety of, the bacillus of hog cholera!

It is only too well known that microbes are like human beings, in this particular at least; seen from a distance they all look alike. Even Drs. Reed and Carroll themselves have furnished an excellent demonstration of this principle when they write: "On the contrary, we wish to state that placed side by side in gelatin we have been unable to detect any differences in the colonies of the two bacilli with the naked eye, and that it is only by means of the microscope that faint differences can be detected."[2]

I do not deny that between the bacillus icteroides and the micro-organisms that cause hemorrhagic lesions (hog-cholera, swine plague, pneumo-enteritis of swine, etc.) there are certain points of resemblance. This family of microbes is, in fact, so extraordinarily pleomorphic in character that the members of

[1] MEDICAL NEWS, September 9, 1899.
[2] MEDICAL NEWS, September 9, 1899, p. 324.

it present some points of resemblance with practically every sort of micro-organism. As the result of this they have been the subject of very great, almost hopeless, confusion in contemporaneous bacteriological literature.[1] Even up to the present time bacteriologists have not succeeded in establishing with anything like unanimity characteristics by which they can be definitely differentiated, so mutable are their qualities under varying conditions. To raise this question, as Drs Reed and Carroll insist on doing so obstinately, after all that has been said with regard to the isolation and the thoroughly studied characteristics of the bacillus icteroides, may serve as a sport on which to while away time in a laboratory, but it will never assist medical science in the solution of the important problem of the etiology of yellow fever.

Instead of remaining in Dr. Sternberg's laboratory, ever on the hunt for anything that seems likely to hurt the reputation of the bacillus icteroides, laboriously constructing theories that may destroy its significance, Drs. Reed and Carroll would have employed their time much better if they had followed the very practical example of their colleagues of the Marine Hospital Service, who, in order to make control observations on my investigations, went into parts of the country infected with yellow fever. It is at Havana or in New Orleans that a properly critical judgment on my work on yellow fever can be formed, not in the Army Medical Museum in Washington, and especially not under the direction of Dr. Sternberg, who somehow feels himself forced into the unfortunate position of a man, who, not having succeeded in an undertaking himself, pretends to believe that others cannot have been more acute or more fortunate than he was.

As it is now it will evidently be impossible for Doctors Reed and Carroll and myself ever to come to an understanding. Any *rapprochement* of opinions on our part would seem to be precluded by the persuasion that I can not shake off, that Drs. Reed and Carroll either have not been experimenting with the bacillus icteroides at all, or else they do not know how to experiment.

Certain of the expressions they use in their last article would seem to point very clearly to the fact that their experiments were not done with the bacillus icteroides. They say on p. 327 of the MEDICAL NEWS for this year: "True we did state and we wish here to repeat, that, with one exception hereafter to be mentioned, the fatty change found in the livers of the dogs experimented with is not comparable to that found in the liver of human beings who have died of yellow fever, and we may add that there is an almost entire absence of that necrosis of individual liver cells which is so prominent a feature in the human liver."

I do not wish to fill out a long article with excepts from the opinions of well-known bacteriologists who have recently made series of experiments with the bacillus icteroides. I can, however, say at once without more ado that this opinion of Drs. Reed and Carroll is positively contradicted by the results obtained by bacteriologists who live in countries where yellow fever is endemic, and who are therefore in a much better position to know its characteristic anatomical lesions than are my confreres of the Army Medical Museum. De Lacerda, Ramos, Fajardo, Conto, Mendoza, not to mention others, have carefully studied the pathogenic action of the bacillus icteroides on animals and have become completely convinced of the perfect analogy which exists between the hepatic steatosis produced by this micro-organism and its toxins and that which is found in the cadavers of patients who died from yellow fever.

Doctors Reed and Carroll declare in addition that the bacillus icteroides produces in young pigs the characteristic symptoms and pathognomonic lesions of hog-cholera. But in their experiments done at the quarantine station of the Delaware Breakwater, their colleagues of the Marine Hospital service, Wasdin and Geddings, assert precisely the contrary and declare that young pigs are absolutely refractory to inoculation of the bacillus icteroides. I do not wish to doubt their repeated declarations in the matter nor to discredit absolutely all that they have written, but I am becoming more and more convinced that they have been all the time experimenting with the bacillus of hog-cholera, while they have been as constantly under the impression that they have been experimenting with the bacillus icteroides.

The fact reported by them that my serum causes an agglutination even at very high dilution in liquid cultures of the bacillus of hog-cholera demonstrates absolutely nothing. The phenomenon of agglutination has a value only in certain special conditions, even the serum of the normal horse may possess of itself a very high agglutinative power with regard to certain microbes In place of working with a serum prepared artificially from horses, Drs. Reed and Carroll would have done much better had they followed the example of their confrères in New Orleans—Pothier, Archinard, Woodson, and others. These men demonstrated that the bacillus icteroides is agglutinated only by serum taken either from those who are actually sick of yellow fever, or from those convalescing from the disease. Serum taken

[1] W. Selberschmidt, *Annales de l'Institut Pasteur*, p. 59, 1895.

from such patients, however, they demonstrated to be completely inactive in regard to any appearance of agglutination in cultures of the typhoid bacillus, and especially as far as regards the colon bacillus, although, as is well known, this last is practically the ordinary agent of secondary infection in yellow fever. I think that it is entirely repugnant even to the most elementary common sense to suppose that the specific causative agent of a disease of hogs, which is very well known and widely diffused over the world, should always have been found, precisely and as it were regularly, in the sick and the dead from yellow fever in cases studied at Rio de la Plata, in Brazil, in Mexico, in the United States, in Cuba, and in Europe. The supposition is so paradoxical that, even without the considerations which precede it, it practically is decisive of the question at issue. It suffices by itself to destroy the quaint edifice of theory which has been raised up in opposition to the bacillus icteroides in the laboratory of Dr. Sternberg.

Finally, I must mention that even Wasdin and Geddings have described very exactly the curious and very well known method in which the bacillus icteroides develops when cultivated on agar-agar at different temperatures. While no one among the authorities who have studied accurately the protean morphology of the microbe of hemorrhagic septicemia have ever mentioned anything like it in the cultures of these microbes.

With reference to the last objection, that raised by Dr. Novy,[1] my reply will be very brief. The question of the resistance to cold is one that can be passed over as of very little importance in the face of the clinical demonstration and the bacteriological and experimental observations which attest that the bacillus icteroides is the true cause of yellow fever. I have already shown how it is possible that an epidemic of yellow fever may become extinguished at the approach of winter, without it being necessary to admit for this reason that its specific causative agent is destroyed by cold. But if Dr. Novy once concedes that the germs of yellow fever can live even during the winter time in clothing, or in the interior of houses, etc., he must admit that the supposition that they always perish because of cold is theoretically undemonstrable. As a matter of fact every time that an epidemic of yellow fever recurs in the same place in which it was raging before an interval of cold, it can be said that while the germ of the disease has perhaps failed to retain its vitality on the streets and in the open places generally, it has been protected from the effect of the winter temperature in houses, in clothes, and clothing, etc., so that the problem becomes practically insoluble. Dr. Sternberg[1] himself has written: "It is claimed that the epidemic of 1897 in the City of Memphis was not due to a new importation but resulted from the liberation of germs in houses that had become infected during the epidemic of 1878." For cholera also the same law seems practically to hold good. It has often been noted that cholera is more apt to continue during the winter than yellow fever. This is certainly due to the fact that the bacillus of cholera is less fastidious than the bacillus icteroides, either as regards the kind of nutriment it requires, or the conditions of life and of development which it demands. With reference to the other objections urged by Dr. Novy it is not worth while to discuss them in detail. They have an importance entirely secondary, and would, besides, lead to an interminable discussion. The scepticism which Fraenkel expresses with regard to the yellow fever in certain synthetic writings of his cannot be considered to have more value than as a platonic expression of doubt. He does not present the slightest scientific basis to support his gratuitous opinion. In Germany they are a little too much accustomed to very legitimate and very praiseworthy triumphs of German science. They do not easily admit, without a good deal of preliminary delay and restriction, that bacteriologists in other countries may also be able to make genuine bacteriological discoveries.

As to the doubt expressed by Thoinot, it falls practically into the same category. There is, however, one aggravating circumstance in his declaration of opinion. He makes a comparative review of my first monograph on the subject, and that of the well known Dr. Havelburg, but he does not realize that this last is the most ridiculous, most puerile contribution to the contemporaneous literature on yellow fever that has ever been made. He makes abstracts from both works with evident good faith, and makes it clear that he is not gifted with a very highly developed critical sense.[2]

Finally, I wish to correct an inexactitude into which Dr. Novy has fallen. The antitoxic serum

[1] MEDICAL NEWS, September 23, 1899.

[1] "Report of Yellow Fever," p. 49, 1899.

[2] Dr. Havelburg made his experiments by inoculating directly under the skin or into the peritoneal cavity of guinea-pigs the intestinal contents, or the black vomit, of patients sick with yellow fever, or these same substances obtained from yellow-fever cadavers. The guinea-pigs very naturally died almost at once of septicemia, and Dr. Havelburg had the good fortune to succeed in cultivating immediately, and in pure culture, from the heart's blood of these animals, the true specific bacillus of yellow fever! It is useless to add that this extraordinary bacillus had the unfortunate property of behaving itself entirely and under all circumstances just as does the most classic of colon bacilli. In 1897 it might have been possible for a writer to be still somewhat in doubt with regard to the results of my experiments, but surely he should not have been so ingenuous as to take seriously the windbag that issued from Dr. Havelburg.

used by Dr. Foa in his experiments was not always prepared by him, but is the same as that which I prepared and used in my experiments at Montevideo before any one else. I have never ventured myself to declare positively that any anti-amaryllic serum was endowed with antitoxic properties, since I never succeeded in gathering sufficient evidence of that fact to satisfy myself. I was very willing, however, that Professor Foa should attempt to demonstrate it, and very glad that he succeeded.

This fact may serve to prove once more that in all of my work on yellow fever I may, perhaps, have committed faults by excessive reserve. I certainly never did so by making imprudent affirmations with regard to facts of which I was not sure or had not carefully demonstrated. I flattered myself with the thought that my inevitable adversaries would adhere to the same system. It is needless to say that I have in this suffered from a profound delusion.

It may be that there are still intelligent medical men who think that more light is needed on the etiology of yellow fever. For myself, I must say that very few etiological problems have been robbed of their mystery and demonstrated with as much clearness and rapidity as this one. May I add that no work of serious importance so conscientiously performed as was this one has ever been the subject of criticism so superficial and withal so obstinate as my research on yellow fever has called forth.

SOME PECULIAR PHASES OF TYPHOID FEVER.[1]

By E. G. JANEWAY, M.D., LL.D.,
OF NEW YORK;
DEAN, AND PROFESSOR OF MEDICINE, THE UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

The number of papers promised upon typhoid fever in its different aspects has led me to limit myself in time and subject. I have thought that a brief notice of some of the peculiar aspects in which the disease has at times been observed might be of interest. So far as I can learn, one of the effects upon the nervous system must be very uncommon in this country. It has been my good or bad fortune to meet three cases of tetany developed in the course of typhoid fever. I have made brief mention of two of these in the discussion of the paper upon tetany read before the Association of Physicians, by Dr. F. C. Griffiths, and published in the "Transactions," vol. ix. Those two cases related, the one to a male patient seen at Bellevue Hospital, and the other, a lady seen in consultation with Drs. Dennis and Garmany. In this latter case the disease formed a distressing and embarrassing complication, for the rigidity involved not only the extremities but also the jaws. The feeding, in consequence, became a matter of considerable difficulty. She recovered after a protracted sickness. The third case I saw in the spring of this year in consultation with Dr. Manges of this city. This patient was very ill and suffered with marked tympanites at the time of the development of this complication. He died as a result of perforation of the bowels, his condition at the time forbidding recourse to a laparotomy for the cure.

It is possible that some have encountered cases of this nature, but have considered them rather as instances of marked muscular rigidity than as tetany. Dr. Manges has told me of his intention to publish this last case, and that in written communications which he has had with different physicians of large experience in typhoid fever in this country he cannot find one except myself who has happened to encounter it complicating typhoid. Should any desire a good account of tetany, I would refer them to the masterly article by Trousseau in his work on clinical medicine, though the therapeutics have changed, and to the additions in the works on nervous diseases published since that date, Trousseau, you will find, speaks of its occurrence rather after than during typhoid. At times, moveover, probably owing to individual idiosyncrasies, the mental state is rapidly altered in typhoid fever, so that patients are supposed to suffer from mania or melancholia, or possibly from puerperal insanity. It has been my fortune to witness patients in the early state of typhoid fever where the question of the first mentioned condition was entertained, instead of the disease which had initiated the phenomena through its influence upon the system. A careful study of the physical state of a patient on more than one occasion should prove to a careful observer such associations with perverted mentality as would prevent the diagnosis of insanity. Nevertheless I have in the past seen patients sent to the reception hospital for the insane who had fever. Such psycho es should be considered totally apart from the delirium proper of the disease, which occurs toward the late period of the illness, and in fact they need a different method of treatment.

Allied to this mental state is also the suicidal tendency which at times is developed in typhoid fever. Such complication may apparently come out of a clear sky, but it should be kept in mind as a possibility and guarded against if the least suspicion of its approach arises; for no more sad affliction can befall the friends of the patient. It would be a wise rule never to leave a delirious patient alone, never

[1] Read at the Sixteenth Annual Meeting of the New York State Medical Association, held at New York, October 24–26, 1899.

to have windows, more especially if on an upper story, so arranged that the patient can get out, and never to have pistols, razors, knives, etc., in such proximity to a feverish delirious invalid that he could readily use them should an insane impulse seize him. It is not enough to have an order given that the attendants shall not leave a patient under these circumstances, but to provide such accessory help as shall make it possible that the rule shall be enforced.

I should like also to speak of two eruptions which have had considerable interest for me in typhoid fever. Herpes labialis is of such extreme infrequency in typhoid fever that its presence in a suspected case makes me carefully revise the diagnosis. On not a few occasions, when I have noted it in cases which I had been told were probably typhoid fever, has its presence seemed to make me give to the case a more than ordinarily rigid examination. This has resulted in usually discovering a hidden pneumonia, cerebrospinal meningitis or malarial fever as cause instead of typhoid. Herpes is not impossible in typhoid, but improbable. For a considerable period I had seen a number of cases of typhoid without encountering a petechial eruption as a complication and had felt inclined to say that it did not occur. Later I was obliged to admit its occasional occurrence in the late stages of the disease. The following illustration will, perhaps, show the want of foresight in making a too dogmatic assertion. At a time when some typhus fever was prevailing in New York, I saw in consultation, in the early period of his illness, a young man with a serious fever; as yet it was not possible to name it unless I had chosen the method of Chambers and dubbed it typhoid fever. I told the physician in attendance that taking all the conditions into account it would in all probability be typhoid, but that if a petechial rash should develop in a few days we would be obliged to consider it typhus fever. A little later I was asked to come again as a petechial rash had been observed. To my surprise, however, I found that a catarrhal jaundice was present as a complication, and with this he had developed an erythema, in the center of the patches of which, in not a few places, were petechiæ. There was not the rash characteristic of typhus. All the phenomena at that time, and the subsequent course sustained the diagnosis of typhoid fever. Again toward the end of typhoid fever hemorrhagic tendencies may develop and petechia occur. The strangest aspect I have seen produced is that which may develop under the coils of the cold water tubes, if such are too continuously applied to the abdomen in these cases. Wherever the coils have lain a thickly set crop of petechia may be present with intervening sound skin producing an appearance of circular rows of blood extravasation. I might add that when these hemorrhagic tendencies occur I have found the tartrate of iron and potash of service.

The onset of typhoid fever in women during the puerperal period has been in my experience a source of serious anxiety to the physician until the proper diagnosis was established. In one case more especially all the circumstances seemed to point toward septic rather than typhoid fever. A woman was delivered with instruments, by a demonstrator of anatomy, before a class of students in a college amphitheater, and within thirty-six hours after confinement developed a fever. For some days the source of this fever was uncertain, though the complete absence of proof of inflammatory conditions in or about the uterus seemed to warrant the hope that the possibility of infection from the conditions named had made the physician unduly alarmed. The patient became early violently delirious, developed diarrhea, and died of exhaustion. The autopsy showed death due to typhoid fever, and entire absence of inflammatory conditions about the uterus or adnexa. The consideration of this diagnostic problem has been forced upon me six times. In one other the fever developed on the day of confinement, which occurred in the Emergency Hospital of this city.

Another problem will at times occur owing to pain in the right iliac region. Pain and tenderness in this situation may be greater than usual not alone at the outset of a typhoid fever, but also in the early period of a relapse. Thus with fever may occur a possibility of mistake in diagnosis between typhoid fever and appendicitis. In fact, I have met or had knowledge of seven cases in which either the appendix was removed or a laparotomy performed, and the appendix not removed because normal, or the operation proposed in typhoid fever at the early stage or in the commencement of a relapse. Moreover, I have been consulted in one case to decide whether there was typhoid fever or appendicitis in a young woman of sixteen because of chills, fever, and pain and tenderness on the lower right side of the abdomen, which was dependent upon a sapremia due to a retained menstrual flow. Whilst early operation is desirable in appropriate cases of appendix inflammation, it is certainly a great error of judgment to remove the appendix in the early period of typhoid fever because of the liability to diagnostic error, and of the haste necessary to operate in uncertain cases. The study of the history of the case, an examination of the number of leucocytes, a careful physical examination with especial attention to

the size of the spleen and the presence or absence of roseola, will in most cases help in establishing a correct diagnosis. The absence of leucocytosis would favor the diagnosis of typhoid, whilst a decided leucocytosis would be against typhoid fever, as the condition or as the sole condition. Of course, I am aware that in rare instances the appendix may give rise to trouble in typhoid fever. The leucocyte count has helped me decidedly in two cases in this category, though in one I was unable to see the patient until the second day, but had required a count of the white cells while waiting. The twenty-four-hour's delay was as helpful. There was no leucocytosis, and the pain and tenderness had disappeared from the right iliac fossa by the time of my visit. The patient went through a relapse of typhoid fever.

Two conclusions, moreover, have been forced upon me as the result of observing a large number of persons infected with fever in institutions. When the subjects are young and but a meager history has been kept, a simple observation of a considerable number may not enable the medical observer to decide positively whether he has to deal with typhus or typhoid fever, provided that from the knowledge that typhus fever exists in the vicinity he is aroused to suspect it. Again when typhoid fever breaks out in an institution, particularly among young people, a considerable proportion of those attacked will not develop the complete disease. While perhaps the word abort may not be the most correct, it most fully expresses what I have observed in this regard at outbreaks in the Deaf and Dumb Asylum of this city, the Catholic Orphan Asylum, and in another institution. Of a large number becoming sick with much the same symptoms, in as considerable a number as one-half the fever would subside within three to ten days. The observation of this occurrence on several occasions has forced me to believe that we have a typhoid febricula though we are only able to rightly recognize it when a number of others subject to identical conditions become ill in the same way, at the same time, but proceed to the full development of the malady. I have long desired to have such cases tested for Widal reaction, but no opportunity has been afforded. Such a conclusion shows how erroneous is the reasoning of those who at the beginning of a fever immediately dub it typhoid fever and after medication of a special kind claim that the disease was aborted by the measures employed. In the cases of which I make mention Nature was the aborter, if I may so express myself.

This leads me to mention two conditions which are observed occasionally in the early period of typhoid fever. The first consists in an attack of stomach and bowel trouble with fever, or fever without these, which subsides in one to two or three days. This leads the physician to suppose that the case was one merely of some intestinal intoxication, grippe, malaria, etc. But after a short period of time the patient passes into a regular typhoid fever. The observation of cases of this nature each year has led me to feel assured that, directly or indirectly, the typhoid organism has been responsible for such occurrence. So also again at times it will be found that without antipyretics there is a drop of temperture toward the close of the first week or in the early part of the second week lasting for a considerable part of a day. My first attention was drawn to this at a time when relapsing fever prevailed in New York City and I had hoped that a patient who seemed to have typhoid might instead have, owing to this, relapsing fever, but the rise in temperature was present the next day and the case continued as well defined typhoid, terminating fatally by intestinal hemorrhage at the close of the second week. Rarely since then have I met this same peculiarity. Observations of this nature demonstrate the need of continued care where any suspicion exists of the development of typhoid fever.

A number of other conditions suggest themselves as of interest, but I will mention only one other of considerable importance. I advise that in office practice rectal temperatures should be more frequently used not only in the first stage of typhoid, but also in other febrile conditions. The temperature of the mouth may be normal while that in the rectum shows the true condition of affairs. Not a few patients, who come to a physicians office with headache and malaise would be sent home instead of receiving a prescription to relieve an engorged liver, or remove a rheumatic or gouty condition, etc., were rectal temperatures more frequently employed in office practice.

TYPHOID FEVER AS SEEN IN BELLEVUE HOSPITAL.

By A. ALEXANDER SMITH, M.D.,
OF NEW YORK;
VISITING PHYSICIAN TO BELLEVUE HOSPITAL AND PROFESSOR OF THEORY AND PRACTICE OF MEDICINE, UNIVERSITY AND BELLEVUE MEDICAL SCHOOL.

In a charity hospital like Bellevue, the patients whom we see come largely from the lower walks of life. A small minority, perhaps, have been in better social conditions than going to such a hospital would imply, but who may have been unfortunate. While, as has been often observed, the most of the cases of typhoid fever at Bellevue come during the months of August, September and October, there are years in which one or more patients suffering

with typhoid fever may be found in every month.

It is always our endeavor to trace, as far as possible, the etiology of every case. This can be done with very little difficulty in the majority of instances, either from the patient himself or from his friends. We are always interested to ascertain if possible if the patient has contracted his illness in the city. In a pretty large proportion of cases we can get a history that the patient has been out of the city for a longer or shorter time, within a comparatively recent period before his attack of illness. Even if the patient has been out of town for a day or a part of a day at a time, we assume an exposure to the bacillus while on such a visit. It is not always possible to obtain accurate information on this point. The patient is asked if he has been out of town during the past few weeks? He will usually answer, no; he has not, but when we come to question him more closely, we find that perhaps he has been out of town for a few hours on Sunday; and this custom of going out of town a part of the day is common, even among the poorer classes. But, in a small minority of cases, we get positive information that the patient has not been off Manhattan Island for months.

It is believed that Croton water is free from the typhoid bacillus. In some instances it is probable that the source of infection is contaminated milk; sometimes perhaps from vegetables or other articles of food; we are even willing to admit that the beloved bivalve may be responsible for an occasional case. With all care and giving all attention to the question of etiology, we are met with the fact that in a certain proportion of cases it is impossible to trace any reasonable etiology.

The cases to which I shall refer were observed in the wards of the Third Medical Division of Bellevue Hospital. This is one of the four medical divisions of the hospital. There were 104 cases with 10 deaths; a mortality of 9.6 per cent. Of these 104 cases the histories of 87 only were sufficiently accurate to make any tabulation. Of these 69 were males and 18 females. The ages of these patients ranged from fourteen to fifty-nine, 17 cases from fourteen to twenty.

(I ought to say that this period is only six years, because patients under fourteen years of age are not taken in the regular medical wards of Bellevue Hospital, but are assigned to the children's wards.)

From the ages of twenty to thirty there were 54 cases; from thirty to forty, 12 cases, and 4 were over forty years of age.

Occupation.—Artisans 14, laborers 20, domestics 12, housewives 8, messengers 11, soldiers 5, students, salesmen, etc., 14, not stated 3.

Social Status.—I group under this head all information obtained from the personal history, the occupation of the patient, the condition in life, the surroundings, the opportunities for obtaining proper food, etc. It is sometimes necessary to obtain this information from friends of the patient.

Poor condition, 28 to 33 per cent.; fair condition, 44 to 53 per cent.; good condition, 11 to 14 per cent.; not stated, 4 per cent.

Necessarily the standard of social status in a charity hospital must be low. These percentages are therefore relative only.

Physical Condition on Admission.—The proportions may be summarized as follows: poor, 24 to 29 per cent.; fair, 35 to 42 per cent.; good, 24 to 29 per cent.; not stated, 4 per cent.

Use of Alcohol.—These may be divided in four groups, thus: abstainers, 34 to 43 per cent.; in moderation, 30 to 38 per cent.; immoderate, 15 to 19 per cent.; not stated, 8 per cent.

Where the statement is made "not stated" either the patient was not in condition to give the history or the friends could not give it.

It will be noticed that the percentage of the immoderate use of alcohol is not high. In almost any other class of cases in Bellevue Hospital, particularly among males, the percentage of those who use alcohol immoderately is very much higher, as is strikingly illustrated in pneumonia, where the percentage of the immoderate use of alcohol is between 60 and 70.

Initial Chill.—Of the initial chill or decided chilly sensations patients are apt to give an indefinite history, but care was taken to get as definite statements as possible. The figures show:

Chills or chilly sensations absent, 35 to 43 per cent.; chills or chilly sensations present, 46 to 57 per cent.; not stated, 6 per cent.

Condition of Bowels.—Diarrhea, 50 to 57 per cent. constipation, 20 to 24 per cent.; regular, 15 to 1 per cent.; not stated, 5 per cent.

The percentages of the conditions of the bowels vary very much in different years. In some years the percentage of patients with diarrhea is very much larger than in others. If there have been more than two movements of the bowels per day the record was made that there was diarrhea.

Epistaxis.—This symptom was absent in 47 cases, fifty-nine per cent.; present in 33, or forty-one per cent., and not stated in 7 cases.

Eruption (Rose Spots).—Absent in 20, or twenty-three per cent.; present in 67, or seventy-seven per cent. This, again, varies very much in different years. In some years the percentage of cases in which the eruption occurs is small; in other years it

is large. In some instances the eruption will be very abundant. There were two cases in which the eruption covered the body to such an extent that it led to doubt as to whether it was the typhoid eruption. One patient in particular looked almost like a child covered with the eruption of measles. The fever ran a mild course in this patient, and he recovered. In another case the eruption was very abundant, and some of the spots of eruption became petechial. This was a very severe case, and the patient died.

Enlarged Spleen.—Careful examination showed it to be absent in 20 cases, twenty-three per cent.; present in 67 cases, seventy-seven per cent. The enlargement was determined by palpation, percussion, or both. In some of the cases patients were brought to the hospital at a stage in the disease when the spleen had diminished in size to normal or nearly so.

Widal's Blood Reaction.—This more recent diagnostic test was absent in 10 cases, eighteen per cent.; present in 49 cases, eighty-two per cent.

Ehrlich's Diazo-reaction in the Urine.—The characteristic reaction was absent in 15 cases, twenty-six per cent.; present in 44 cases, seventy-four per cent. The figures for the Widal-test and the diazo-reaction were taken from the last 59 cases. In 6 cases the Widal test was present, and the diazo-reaction absent, whereas in 5 cases the Widal test was negative and the diazo-reaction present.

Albumin in the Urine.—This was determined to be absent in 26 cases, twenty-nine per cent., and present in 61 cases, or seventy-one per cent. One case of true nephritis was observed.

Relapses.—Relapses occurred in 8 cases, nine per cent.; all recovered. In 1 case there were three relapses; in 2 cases there were two: in the other 5 but one relapse. The duration of the relapses varied from nine to twenty-two days.

Fatal Cases.—Of the 10 patients that died, 3 were laborers, 1 an artisan, 2 were domestics, 1 was a messenger, 2 were housewives and 1 a soldier. Seven were males and 3 females. In 4 the social status was poor, in 5 it was fair, and in only 1 was it good. In 6 the condition on admission was poor, in 2 it was fair, and in 2 it was good.

Complications and Sequels. — In four of the cases there was pregnancy. All recovered without aborting. There was chronic endocarditis in one case with recovery. Pneumonia and nephritis was present in one case. This patient died. In one case there was unilateral parotitis. It was only moderately severe and resolved without suppuration. Laryngitis with edema glottidis was a fatal complication in one case. Double otitis media was present in one case, while in five cases plasmodium malariæ was demonstrated during convalescence. Phlebitis occurred in three cases. In two of these it was single, both on the right side, and both involved the internal saphenous vein. The third case was a double phlebitis, involving the femorals. The patient recovered after a long period of sickness. In none of the cases was there gangrene. There was orchitis in one case. Four patients were addicted to the immoderate use of alcohol, three were moderate drinkers, and two were abstainers. Both of these latter were women. In one of the fatal cases it was impossible to obtain information with reference to the use of alcohol.

I might mention in this connection a case which aroused much interest in the hospital, although not occurring in the Third Medical Division. A patient had had a moderately severe attack of typhoid and had convalesced slowly without any special features, and on the 28th day of his convalescence he was sitting in an arm-chair reading a paper. He had advanced sufficiently to be dismissed from the hospital and was simply waiting until the next day to be dismissed. He got up from his chair, suddenly had a severe pain in his abdomen, fell over in collapse and died in a few hours. The autopsy revealed a perforation.

Cause of Death.—The actual causes of death were as follows: Perforation, 2; pneumonia, 1; excessive high temperature, 2; laryngitis, with edema glottidis, 1; peritonitis, from the officious interference on the part of the house physician, 1. This last case was a very severe one, and had as a complication double otitis media. So far as the otitis was concerned the patient was apparently progressing favorably but had persistent tympanites. The house physician, without consulting the visiting physician, with a hope of relieving this tympanites, aspirated the intestine. The patient promptly developed acute peritonitis and died; autopsy showed the peritonitis as having apparently developed from this puncture. Three died apparently from exhaustion due to toxemia. One of these a woman of fifty-nine—fat and flabby. Decided hemorrhage occurred in only two cases, both in the third week. These patients recovered. Slight discharge of blood occured in several other cases, but not of sufficient quantity to be called a hemorrhage.

The highest temperature recorded was $106\frac{3}{5}°$ F. In another case the temperature reached $106\frac{1}{5}°$ F. Both of these cases obstinately resisted all efforts to reduce temperature. They are the two cases referred to among the fatal cases as dying from excessive high temperature.

Treatment.—Baths were resorted to in 48 cases; drugs and other forms of treatment in 39; the av-

erage number of baths was 20, though they ranged from 2 to 92 in number. In some cases the disease ran such a mild course that practically no treatment was resorted to.

The treatment was usually initiated by a dose of calomel, followed by a saline cathartic. This was, perhaps, repeated during the first week of treatment once in forty-eight hours, depending on the effects produced. Usually after the first week, if constipation was a prominent feature, as occurs in a considerable proportion of the cases, enemas were relied on for its relief. For the relief of the tympanites salol or beta-naphthol were relied on for internal medication. If diarrhea was a marked feature some form of bismuth, preferably the subgallate, was added. For external application for relief of tympanites, hot turpentine stupes or the cold Leiter coil was used. If the patients were seen during the first week and wakefulness was a prominent symptom, with decided delirium, hypnotics were used. These were specially indicated in many of the decidedly alcoholic cases. If the wakefulness was pronounced and headache severe some preparation of opium would answer a better purpose in giving relief. Sometimes the ice to the head was resorted to with relief.

As stimulants, alcohol, in the form of whisky, strychnin, and caffein were relied upon. The last in only a few instances. Only in pronounced alcoholic cases was alcohol commenced early; in the other cases alcohol was resorted to only when there were special indications, as shown in the condition of the pulse and nervous system. Alcohol was not used indiscriminately, but only in cases which specially indicated it. It was used most freely in the cases showing the restless wakefulness of exhaustion, or in the exhaustion of the nervous system or circulatory system. Rarely was it necessary to use more than 6 or 8 ounces in the twenty-four hours. In exceptional cases, perhaps, that was increased to 10 or 12 ounces. The alcohol was stopped as soon as indications for its further use were past. Water was given to the patients freely. Milk formed the main article of diet throughout the course of the attack. Animal broths, well salted, were allowed once or twice a day. In some cases the white of an egg would be added to a glass of milk three or four times a day. In cases of alcoholics, where the gastric irritability was pronounced, and even milk produced disturbance, Vichy was added to each glass of milk in the proportion of 1 part of Vichy to 3 parts milk. In some cases, when the milk was repulsive, koumyss or matzoon was substituted with very satisfactory results. This was the line of diet until convalescence was established, and even then great care was shown as to the giving of solid food. The plan followed was to continue this line of diet for eight or nine days after the temperature had touched normal. I mention this fact because of our unfortunate experience in the attempts to resort to solid foods earlier in convalescence, as is the method followed by some excellent observers.

CLINICAL LECTURE.

VARICOCELE, MOVABLE KIDNEY, MAMMARY CARCINOMA, RECURRING APPENDICITIS.[1]

BY CHARLES McBURNEY, M.D.,
OF NEW YORK.

GENTLEMEN: I wish first to show you to-day two of the patients who were operated on last Saturday. This young man was operated on for the cure of a right inguinal hernia by Bassini's method and for a varicocele in the usual site on the left. The wound made for the radical operation of hernia is doing very nicely and no further comment is required. The varicocele operation has been equally satisfactory in its results. I did in this case the operation which I always now do in similar cases. After incising the scrotum and dissecting out the large plexus of distended veins, two catgut ligatures were placed around these vessels at a distance from each other of about two inches. Care was taken of course not to include in these ligatures the plexus which accompanies the vas deferens. The mass of enlarged veins between the two ligatures was then incised and the ends of the ligatures tied so as to bring the stumps in apposition. A few approximating stitches of catgut were also applied. We find now at the point of apposition an inflammatory thickening. This is a good sign and practically assures the success of the operation. I have never had any accidents with this form of procedure for varicocele and recurrences in my experience are practically unknown.

After his getting up, which I shall allow in about two weeks more, I shall not ask the patient to wear any supporting apparatus for his hernia. He may go without a truss. I shall, however, recommend him to wear a support for his testicles for two or three weeks in order to prevent the stretching of the recently united tissues.

MOVABLE KIDNEY.

The patient who was operated upon last Saturday was a young woman who had the typical symptoms of a movable kidney. There was almost continuous abdominal discomfort that at times became positive pain. There was persistent gastric disturbance, with nausea and loss of appetite, and there was constantly recurring headache and a readily movable tumor, evidently the right kidney, could be felt in the right loin. In the operation that I have found of most benefit in these cases, the only one in fact which seems to secure the patient against relapses, the incision is made, as in this case, parallel to the last rib and about one-half inch below it, here in the lumbar region. The incision is carried down to the perirenal fat, which is

[1] A clinical lecture delivered at the Roosevelt Hospital.

notched with scissors and then torn open, exposing the kidney in its capsule. The capsule of the kidney is split and stripped off from the organ for some distance; its cut edges being fastened to the deep edges of the muscular wound. The wound is then packed, the gauze being carried down to the kidney itself. The plan is to prevent union of the external wound by first intention and to set up a certain amount of irritation, that will cause the formation of new connective tissue around the kidney, and so fasten it to the abdominal wall. When we remove the gauze here, you can see the kidney very plainly at the bottom of the wound. Normal aseptic granulation tissue can be seen covering the exposed surface of kidney. Instead of moving up and down in wide excursions with the respiratory movements as it did before the operation, and as is usual with movable kidney before adhesions are formed, it now lies motionless. The patient of course will be kept as quiet as possible for about three weeks longer, when the adhesions will have become very firm. The external wound will then be allowed to close and I do not expect the patient to ever have further symptoms due to mobility of this kidney.

This operation is very safe. I have never had an accident with it, and I think it can be recommended with the perfect assurance that it will not give rise to any serious complications. These cases of movable kidney can be radically treated only by means of an operation similar to the one described. Since I did this operation I have seen a young woman who has suffered for nineteen years with aggravated symptoms of movable kidney. In her case the mobility of the kidney is due to a series of violent falls occurring at the age of seven years. It is very unusual for movable kidney to develop at so early a period, and only some uncommon cause could have led to it. In this case I assured the patient that practically all of her symptoms could be removed by the operation, that there would be very little risk, if any, and no danger of return.

CANCER OF BREAST.

Our next patient is a woman forty-three of age, who has had four children and who noticed a feeling of discomfort in her left breast about a year ago. This has gone on increasing. Examination disclosed the fact that there was not much pain, though there was some tenderness. The entire breast was densely indurated. The nipple was much retracted, dragged down into a deep furrow in the skin. Further examination showed that there were a number of enlarged glands in the axilla, though none could be found above the clavicle. In the skin around the nipple certain nodules, shot-like in character, could be felt. These signs taken in conjunction with the history permit one to make an absolutely positive diagnosis. We have to do here with a fibrous carcinoma of the breast.

Suppose we first ask ourselves what would be the natural history of the case if it should be left untreated. There is no absolute law by which we could foretell what length of life would be left to the patient, nor just what course the cancer would take in its development. It is certain, however, that the disease inevitably progresses, and that the fatal termination would come in two or three years or less. In the meantime she would suffer a great deal from pain and mental distress, with disability of the arm and internal complications. Even if we forsee that operation is likely to be only palliative, it is still indicated in these cases. When we cannot promise a cure we can at least assure amelioration of the patient's condition, and some hope even that recurrence will not take place. We can never assure our patient's that operation in any given case will be followed by positive cure. Even small malignant tumors may already have given rise to metastases, which will later lead to inevitable diseases.

The characteristic of carcinoma which is most important is its tendency to disseminate itself through the body, making use for this purpose especially of the lymph channels. Because of this peculiarity a carcinomatous process very soon finds its way from the breast itself into the lymph passages leading from it, and at an early date is found in the lymph glands of the axilla. In a very large percentage of cases axillary involvement occurs very early. At a later stage the supra-clavicular glands become diseased. In certain cases the pectoral muscles are involved or the pleura is attacked. The lymphatic tissue in the anterior and posterior mediastinum may become infected. From here involvement of the viscera readily occurs.

These considerations modify the prognosis to a very great degree, so that practically in no case can we positively promise a radical cure. We are, nevertheless, usually able to afford a great measure of relief to certain annoying symptoms. We can, for a time at least, lift a load off the patient's mind, and in many cases by prompt and thorough work produce a radical cure. Our recognition of the methods by which carcinoma disseminates itself has led to marked improvement in these late years in the methods of operation, and this has largely increased the number of radical cures. It is, of course, an extremely unfortunate situation when the patient comes to us at a time when so much dissemination has already taken place that the hope of eradicating the disease and its outlying processes in the lymphatics is almost surely at an end. Yet even in these cases we can afford our patients so much relief that operation is usually indicated.

There is a period in every case of carcinoma when the affection is absolutely local. If all patients could be operated upon during this period the statistics of the results would be totally different from what they are. The sooner that operation is done after diagnosis is assured the better. The conclusion that must be especially impressed upon you is that the very earliest symptom of a possible cancerous growth must not be neglected. A positive diagnosis must be made either from physical signs, or from a microscopic examination after excision of a portion of the tumor. If this were done in every case we would not have to bewail our ill-success in operations for mammary cancer, and the statistics of our radical cures would rapidly improve. Unfortunately there is often some member of the family, sometimes the patient, sometimes even the family physician himself, who is ill-

advised enough to consider very early operation unnecessary. When this impression has been gotten rid of, the death-rate from cancer will notably decrease.

The operation for cancer must be planned with the recognition of its tendency to dissemination always in mind. Not only must the original tumor be removed, but also as much surrounding tissue as is possible without too great danger to life or too serious disability from mutilation. The lymphatic channels must be carefully followed and as far as possible thoroughly eradicated. This makes a large dissection necessary, but it is perfectly justified by the gravity of the condition and by the fact, now so well known, that this is the only course which gives any hope of permanent freedom from recurrences.

The incisions should be so arranged as absolutely to remove all skin overlying the tumor which could have been infected from the cancerous growth. In this case we have nodules of cancerous tissue in the skin to emphasize the necessity for this, but even in cases where such appearances are not so manifest the rule with regard to the removal of suspicious cutaneous tissue must always be borne in mind, for it is in the skin especially that recurrences are prone to take place. In making the incision and in removing the portion of the skin overlying the tumor, no regard should be paid to the fact that the skin-edges may not come together when the operation is over. This question is of very secondary importance.

As we know that the axillary glands are involved we shall remove all the connective tissue and all tissue containing lymphatic structures in the axilla. In order if possible to avoid the danger of recurrence from backward extension of the cancer we shall remove a large portion of the pectoralis muscles. To do less than this would be to do injustice to our patient. If we were to do more there would be first the risk from the seriousness of the operation and then the deformity from the mutilation and consequent disability. There are good reasons for limiting the operation to the tissues indicated. It seems but just to say that with this extensive operation for mammary cancer, which of late years has become so popularized, the name of that distinguished surgeon, Halsted of Baltimore, is intimately associated. He not only devised and developed the operation on scientific principles, but showed the profession the benefits that might be obtained from its application. To those of you who have never seen the operation before it may seem to involve too extensive dissection and mutilation. But if you should see the patient later on, you will find, first, that the recovery is rapid and is usually without incident; and, secondly, that the disability resultant from the removal of so much tissue is extremely small.

The incision that I make is carefully directed so as to avoid the leaving of a scar across the axilla. In the older operations for removing the contents of the axilla in cases of cancer in the breast, this scar was very prominent. Its contractile nature caused the tissues here to pull together, and interfered with movement of the arm. Instead of carrying the incision upward into the axilla it is directed more toward the end of the clavicle, and then is carried somewhat down the arm. It follows in general the line of the pectoralis muscle. When the upper flap is dissected back it is easy to make a very thorough exposure of the upper part of the pectoralis major muscle. When the lower flap is dissected back to the posterior line of the axilla it is possible to open up the entire axillary space very thoroughly and without difficulty. This lower flap is made as thin as it can be without risking the vitality of the skin. If it is allowed to be too thick there is risk that cancer nodules from the axillary tissues may be included in it, and recurrences will be inevitable if the slightest bit of cancerous tissue is allowed to remain. Between these two extremes of a thinness which might be insufficient to nourish the cutaneous tissues, and so lead to gangrene of the skin, and a thickness that might risk the leaving of even a single cancerous nodule, the surgeon's experience must guide him.

As we dissect backwards here we begin to see the edge of the teres major muscle. This shows us that we have gone far enough in this direction. We make the incision well down to the layer of muscles. The pectoralis major and serratus magnus may now be seen uncovered at the bottom of the wound. It is necessary to go at least as deep as this. A very important part of the operation consists in guarding as far as possible against blood loss at this stage. I have never had a death from this operation, and it is always well borne, even by those who are not in very robust health. There are, however, a number of blood-vessels here in the deeper part of the wound which require to be carefully ligated. In dissecting back the upper flap it is advisable to keep as far away from the breast as possible so as to avoid leaving any cancerous tissue behind. Lymphatic ducts and glands at some distance from the breast are very liable to be affected. To leave any of them means inevitable recurrence.

The advantage of the incisions which I have made will be seen, especially when we come to the direction of the axillary space. By the old method, with the incision straight across the floor of the axilla, axillary tissues could be removed, but their complete exsection was practically impossible. We have here at the upper angle of the wound the clavicular fibers of the pectoralis muscle laid bare. If we pass our fingers beneath these fibers we can cut through the muscle without danger, and when we do so the axillary space is laid open for a thorough dissection. We have the fascia underlying the pectoralis muscle still covering the contents of the axilla. This is carefully divided and the deep dissection begun. The axillary vein can be seen very plainly, and one should be specially careful of it. It forms the outer limit of the dissection, and in general all tissues inside of it must be taken away except certain nerves, which, because of their functional importance, we shall try sedulously to preserve.

At this stage of the work a number of pectoral branches of the veins and arteries are met with. Like all vessels situated somewhat deeply, these are very delicate and easily torn and they should be tied as soon as they appear. Now the pectoralis minor muscle comes into view and this is also divided, as doing so makes it much easier to get at underlying tissues. Dissection beneath the

muscle without section of it would be an imperfect procedure and one could not be sure that all infected tissues were removed. Thorough removal of such tissues is the one thing absolutely necessary.

It would not do merely to cut and seize with clamps the mouths of bleeding vessels at this stage of the operation and then let these lie as we do with the vessels nearer the cutaneous surface. All small vessels which lie deep in the tissues as these do, are, as I have just said, very delicate and easily torn. If clamps were allowed to hang on them, either the vessels themselves would tear or perhaps a hole would be torn out of the side of one of the main veins. This is, of course, an extremely undesirable complication and one that might have serious consequences. It occupies some time to pass an aneurism needle beneath each of these vessels and tie it before cutting, but it is very important that this should be done, as loss of blood is avoided, which is a most important consideration, especially in prolonged operations.

It is at this stage that we must look for certain important nerves. I have here the long, subscapular nerve, which supplies a very important muscle, the latissimus dorsi, and the nerve must be spared in order to preserve the function of this muscle. I clean the nerve thoroughly, remove all the connective tissue lying around it, but leave the nerve itself uninjured. I have now removed in one mass the entire contents of the axilla excepting the large vessels and nerves, and you can see here the bare surface of the serratus magnus muscle. After this we work toward the breast and continue to turn back, farther and farther, the pectoralis major and minor muscles. I remove the whole breast with the fatty tissue lying around it, the skin above it, the two pectoralis muscles, and all of the axillary contents. I do not cut the sternal attachment of the pectoralis major muscle close to the bone and intercostal spaces for, if I did so, the perforating branches from the internal mammary artery would be severed so close to the intercostal membrane that it would be very difficult to ligate them. It is best, therefore, to sever the muscle on a line about ½ inch distant from the muscular attachment to bone. The perforating vessels are thus cut quite long enough to permit of satisfactory ligation.

While it is not essential to drain these cases, I have always considered it advisable to leave a drainage tube in the wound for twenty-four hours. Not that I feared infection, but there is often some accumulation of blood. Tension is relieved, a very suitable culture medium for micro-organisms is removed, and the healing of the wound is favored. Besides this after the first sutures have been put in a thin strip of gutta percha tissue is inserted at each angle of the wound. While the wound would heal very well with only these interrupted sutures, it heals very much better, more evenly and more quickly, if the skin edges are carefully brought together by an apposition suture throughout the entire length of the wound. I must insist once more that the mere closure of the wound after operation is a very secondary consideration and not to be weighed at all in comparison with the desirability of getting rid of a possible focus of disease which may exist in the skin. If a single cancer nodule is left in the cutaneous tissue it will be prone to develop into a serious lesion.

You have seen how much muscle has been removed in this case, and you probably think that considerable disability will result. If you should see this patient a few months from now you would be surprised to find that the movement of her arm, will be quite as good as that of the other. The clavicular fibers of the pectoralis major muscle and the anterior fibers of the deltoid are quite sufficient for function. Even the deltoid alone will suffice to accomplish these motions and I doubt that you would be able to distinguish by ordinary functional tests from which side the muscles were removed.

In dressing the wound a very efficient bandage is this many tailed bandage which we use here. It is similar to an ordinary many-tailed bandage with a wide, firm piece at the back, and then two tails that go over the shoulder from the upper part of the wide back-piece and one from below which comes up over the arm below the elbow. This secures the arm very completely to the body and effectually prevents all motion during the early days after operation.

RECURRING APPENDICITIS.

The next patient is a boy of eleven years, who has had several attacks of illness with a very definite set of symptoms. These symptoms were very characteristic. Severe abdominal pains were complained of during the first few hours of each attack, and at the end of about twelve hours the pain became distinctly localized in the right iliac fossa. Each attack was accompanied by some nausea, by fever, and by heightened pulse-rate. He had his first attack several months ago and recovered completely from it. But afterward he had a series of recurring pains mainly referred to the right iliac region. After about three months he had a second severe characteristic attack.

This boy first came under my observation about ten days ago, on the second day of his last attack. His fever on admission to the hospital was 102.8° F., his pulse-rate 124, and when he came here the pain had already become localized in the right iliac fossa. Excessive tenderness was noted at a point about midway between the umbilicus and the right anterior spine. I had no hesitation in diagnosing the case as appendicitis of that type which is known as recurring appendicitis.

The important question on his admission was, will this affection be progressive? was the inflammatory process likely to increase until a collection of pus had formed, or was there a reasonable hope that this attack would terminate as the others had done? These questions were not easy to decide. There are no general rules to guide one at the beginning of an attack of appendicitis in making the differential diagnosis between a case that may get rapidly worse and one that may rapidly subside. Needless to say, the question is a very important one for the patient and also for his attending physician. A practical decision must be made soon, and I find this about my own rule of practice. If the pain, vomiting, fever,

and pulse rate continue to increase, or even remain unimproved for more than one day, or if I judge from my experience of such cases that the future behavior is very doubtful, I operate as soon as I can obtain permission. If at the end of twenty-four or thirty-six hours there is some remission of symptoms, then I prefer to wait further developments. Not that there is much more danger in operating in acute cases, though it must be admitted that there is some more. In the acute stage, however, we are obliged to make use of an inferior method of operation. We are not able to benefit the patient as surely and as effectually as when there is no danger of the acute localized process becoming generalized by our manipulation.

In this case I concluded that the symptoms were not over-active, the general appearance was not that of a patient seriously ill, the pulse was encouraging on his admission, and so I decided to wait. On the next day the fever had subsided. The following day he felt still better, and to-day you would say that there was nothing the matter with him, and you would only find on rather deep palpation some tenderness in his right iliac fossa.

The subject of appendicitis is too large for me to discuss all its features to-day, but I wish briefly to dwell upon certain practical questions that are of especial interest. First, as to the reason for operating at all, and, secondly, as to when operations should be done in such cases. The fact that a patient has recovered from an attack, or even from numerous attacks, is no guarantee that he would also recover from the next one. There is no assurance in the past for the future. A mild attack may be followed by a very severe one. On the other hand, a severe attack may not be followed by one that is more severe. Occasionally a patient will have one attack, then never have another. A patient may have two or even three attacks, and yet never have another. The occurrence of one indicates a liability to further attacks of the disease, but absolutely gives no definite information in any particular case. The next attack in any patient may prove fatal. Usually succeeding attacks are at least not milder than those that have preceded them. A patient with a damaged appendix has no assurance from attack at any time, and a fatal termination is at least possible.

Under these circumstances the only valuable treatment of the condition is the surgical one. No medical treatment will influence the condition of the appendix in the slightest degree. The diseased organ must be removed on the same principle that a poisonous foreign body should be removed from the body without waiting for it to give rise to general sepsis. The patient must not be advised to wait and see what will be the nature of succeeding attacks. Certain contraindications to the operation do exist. If the patient is very weak or very old so that he will not stand operation well, or if he is very fat, and these conditions would add materially to the difficulties to be encountered in the operation, then, perhaps, operation might be considered more dangerous than the disease. Such cases will rarely be found.

Now as to the character of the operation. Wherever we remove septic material from the body we close up the cavity in which it has been contained only if we have been able to render the cavity perfectly sterile. We close up an abscess, for instance, only if we feel sure that we have dissected away the whole abscess wall. This is evidently impossible in the case of the peritoneum. Hence drainage becomes a necessity. If we employ drainage this leaves a weak spot in the abdominal wall. The granulation tissue that forms under these circumstances has not the strength of the ordinary tissues of the abdominal wall, and will yield to intra-abdominal pressure, and a hernia will result. This danger is always to be feared if we perform the operation in the acute stage. When our manipulations have included a part in which there has been for days before an acute inflammatory process we do not care to completely close the wound. The risk is too great. This is what we would have had to do had we operated on this little patient a week ago. Now, as you will see, we can very easily and effectually avoid this danger.

We make our incision through the skin in a direction parallel to the fibers of the external oblique aponeurosis. This structure is not to be cut, but one should split it and separate the edges of the opening. We then cut the muscular fascia lying above the internal oblique muscle and separate its fibers. The transversalis fibers here run nearly parallel to those of the internal oblique and these also are to be separated. It only remains to pinch up and divide the fascia transversalis and the peritoneum. By this method we have cut no important structures in the abdominal wall and have not weakened its resisting power. After cutting through the peritoneum we come upon the caput coli. As I do not care to make unnecessary manipulations I prefer not to insert my finger and feel about for the appendix, but gradually draw the cecum into the wound when the appendix will soon come into view. I do this, as you notice, cautiously for there may be slight inflammatory adhesions which it would be undesirable to tear. Here I have come upon the base of the appendix. I find in the organ evidence of a comparatively recent inflammation. There is a marked engorgement of the peritoneum covering it and some delicate adhesions due to only partially organized lymph on its exterior.

I now divide meso-appendix, tying it off in sections in order to avoid bleeding. The history of the case would lead us to look for some lesion either within or without the appendix that had lessened the caliber of the organ. There were well-defined symptoms in the recurring attacks of a spasmodic condition such as would be set up by some diminution in the lumen of the appendix and the collection of material behind it trying to force its way out.

The stricture in the appendix may be due to the formation of new connective tissue as in the urethra. This new tissue is under practically similar conditions, or the narrowing of the lumen may be the result of some distortion of the appendix from an external cause. The stricture causes symptoms because beyond the narrowed part either an accumulation of feces occurs, or in the detained fluid of the appendix infection takes place and bacteria develop. After this pressure symptoms progress.

When the bacteria increase in the retained substances there is an absorption of septic material and this causes the constitutional symptoms of the disease. The pain and the tenderness which usher in an appendicitis are due to the rapid development of septic material and the spasmodic contraction of the organ in the attempt to get rid of it. In cases that get well spontaneously the accumulated material forces its way out into the intestine and the remission of symptoms occurs just as soon as evacuation has taken place. A locus minoris resistentiæ is left in the appendix, however, and in addition the original stricture remains so that attacks are liable to recur. Finally a time comes when the material imprisoned in the appendix cannot force its way into the cecum and then there is rupture of the appendix, or necrosis, because of interference with the blood-supply, by pressure of the accumulated material, and involvement of the peritoneum is the result.

In order not to leave any mucous membrane projecting into the peritoneal cavity, which would be dangerous because of its liability to retain infectious material and so infect the peritoneum, we invert the appendix into the cecum and bring the peritoneal surfaces together above it. In order to do this easily we dissect up a cuff of peritoneum and cut the fibrous and muscular coats of the appendix at a lower level, *i. e.*, nearer the bowel. We now test the permeability of the small stump that is left in order to be sure to leave no stricture between the amputated end and the cecum. The probe passes easily. With a purse-string suture we now gather up the wall of the cecum. I always invert the appendix into the cecum. For this purpose I use the little instrument that you see here, which has a shoulder on it. As I push it in, it inverts the stump of the appendix and I am able to draw it out leaving the appendix as a small projection on the inside of the cecum. I now pull the purse-string suture taut and tie it, leaving only a puckered spot where the appendix was. This I consider the best way of disposing of the appendix, and I acknowlege my obligations to Dr. Dawbarn of this city who devised this very ingenious and useful method.

I now close the incision, first suturing the peritoneum and fascia transversalis very carefully. The rest of the wound might really be left to take care of itself, but I draw the muscular fibers somewhat closer together than they would otherwise fall and retain them in this close apposition by a few sutures. I put some sutures also in the aponeurosis of the external oblique muscle. It is very interesting to see the condition of an opening like this, if nausea occurs during the operation. Ordinarily there is pouting of an abdominal wound under such circumstances, but when the opening is made like this one, all of the muscular fibers surrounding it contract and instead of pouting and opening up there is contraction and the opening in the abdominal wall is shut up tight.

I shall now open this specimen, which has been removed in order to demonstrate to you the condition that exists in it. I try to pass a probe and find that it meets with resistance a little beyond the middle of the appendix. Careful, gentle manipulation of the instrument, though continued for some time as you see, fails to get us beyond this point. I now carefully open up the appendix as far as the probe penetrated and can demonstrate to you the stricture that exists. Even now I am unable to pass the probe. Taking a finer instrument I succeed with the aid of vision in getting it past the obstruction. The stricture though tight is still permeable and thus accounts for the remission of the symptoms in the last attack which took place. I now open up the appendix beyond the stricture and find the lumen greatly dilated and containing some dirty purulent fluid which is undoubtedly septic and which would doubtless prove on careful investigation to contain dangerous micro-organisms. When I now cut through the stricture itself, you can see that we have here a very perfect example of a stricture of the appendix which closely resembles a stricture of the urethra. The lesson is a most interesting one and the demonstration of the specimen should, I think, prove to conviction what the pathological lesion is in many cases of recurring appendicitis and how inevitably necessary operation becomes sooner or later.

CLINICAL MEMORANDUM.

LARGE PERINEURAL FIBROMA INVOLVING THE ENTIRE SCIATIC NERVE-SHEATH.[1]

By RUDOLF MATAS, M.D.,
OF NEW ORLEANS, LA.;
PROFESSOR OF SURGERY, MEDICAL DEPARTMENT, TULANE UNIVERSITY OF LOUISIANA.

THE following unusual case of a large perineural fibroma involving the entire sciatic nerve-sheath and deep femeropopliteal fascia appeared of especial interest to me from the fact that extirpation of the tumor and popliteal vessels was performed, leaving the sciatic nerve uninjured, *in situ*, and recovery took place, with the loss of only the toes and heel-covering from sloughing.

The patient, C. B., a light mulatto, was a native of Louisiana, aged twenty-two years; a steamship waiter by occupation. He was distinctly tubercular on the maternal side. His personal history was good as far as habits and previous diseases were concerned. There was no history of traumatism, nor other conditions that might suggest a cause of the present trouble. He was admitted to the Charity Hospital of New Orleans, April 1, 1898, for the relief of a large tumor of the right lower limb, which had gradually developed since the age of twelve (ten-years' duration). The patient was pale, anemic, marasmic from prolonged inactivity, indoor life, and bad hygienic surroundings. He had been losing flesh progressively, and now weighed only 120 pounds, notwithstanding his height which was six feet. The large size of the right lower limb was striking to the eye on account of its great size, markedly contrasting with the opposite member which was thin and atrophied. (See Fig. 1.) The affected limb was enlarged from the lower gluteal fold to the toes. The enlargement was most marked posteriorly, where it projected in prominent relief

[1] Preliminary report presented to the American Surgical Association, annual meeting held at Chicago, May 31, 1899.

from the femoral, popliteal, and crural regions. The tumor increased progressively in size from the tuberosity of the ischium to the center of the popliteal space, where it attained its greatest dimensions, and from this point again decreased until it reached the malleoli. The leg and foot were cylindrical in outline, the normal contour of the ankle having been obliterated by edema which was evidently caused by mechanical compression of the popliteal vessels. The tumor originated primarily in the popliteal space as a slow, indolent, hard, painless swelling which in no manner interfered with the function of the limb until three years ago, when it filled the space back of the knee so completely that flexion was impossible. About the same time it was noticed that the growth had extended up the thigh and down into the calf, but it was not until one year later that edema and weakness of the leg began.

The actual length of the growth as it was felt through the skin was 42 cm. (17.5 inches), and it extended distinctly along the sciatic tract from the tuberosity of the ischium to the middle of the calf. It projected behind the popliteal space from one hamstring to the other, 21 cm. (9 inches). The circumference of the affected limb around the knee was 49 cm. (19.5 inches); of the sound limb 36 cm. (14.5 inches). The same proportional difference was observed in comparing the normal and affected

FIG. 1.

limb at various points in the circumference of the thigh and leg

The skin overlying the tumor was thin, adherent, fixed, and immovable; the underlying mass was hard and nodular, especially in the popliteal space and calf. There was no pain on pressure or spontaneously. There was some edema in the skin of the leg, and a small superficial ulcer above the ankle; no trophic lesions or disturbances

FIG. 2.

Perineural fibroma of the sciatic, involving the femoropopliteal space.

of sensibility could be detected in the foot or leg. The neoplastic area was defined externally by a line drawn from the great trochanter to the external condyle of the femur and middle of the fibula; internally by a line from the tuberosity of the ischium to the internal condyle and middle of tibia. Scarcely any motion was obtained by manipulation, the growth being very deeply rooted to the posterior ligament of the knee, sural and hamstring muscles, and periosteum of the femur.

A cubic fragment of tumor was removed from the popliteal space under cocain anesthesia, and the diagnosis of pure fibroma was established. On May 18, 1898, the tumor was extirpated, *en bloc* by a careful dissection which extended from the tuberosity of the ischium to the middle of the calf; the incision measured about 54 cm. (24 inches). The tumor, which was a white, dense, extremely hard, and resisting mass, had to be removed by

a process of slow and tedious dissection. It was impossible to enucleate or shell it out of its surroundings; it had no capsule; it is blended everywhere most intimately with surrounding tissues. When removed it measured over seventeen inches in length, and weighed a little more than three pounds. (See Fig. 2.) It was hard, bloodless, and creaked under the knife. The origin of the tumor from the sheath of the sciatic nerve was clearly ascertained, and the greatest difficulty was experienced in separating it from the nerve. In the popliteal space the mass had so completely wrapped itself around the popliteal artery and vein that all efforts to save these vessels had to be abandoned, and more than three inches of each had to be removed. The artery being cut off right down to the level of the bifurcation, and with it part of the posterior ligament of the knee, with which the tumor had contracted inseparable adhesions, had to be excised, thus exposing the knee-joint. The peroneal and internal popliteal nerves had to be literally dissected—carved out—from the mass in which they were embedded. The gastrocnemii and soleus muscles also intimately blended with the mass, at their origin, and part of these muscles, with the corresponding sural and articular branches of the popliteal vessels, had to be sacrificed. At this stage of the operation all hope of saving the foot and leg had been abandoned, believing that sloughing of these parts would be inevitable. Nevertheless, after securing all bleeding-points and removing the constrictor it was observed that the foot and leg gradually lost the waxy cadaveric appearance, and that the color and sensibility of the skin of the foot had returned. All pulsations in the pedal arteries ceased, but the color of the skin encouraged us to hope that a sufficient collateral circulation existed to prevent the total mortification of the leg.

The limb was carefully wrapped up in a copious cotton-wool dressing to keep it aseptic and warm, and the vast wound in the thigh and leg was closed with interrupted sutures and drained. A long posterior, padded, gutter-splint (cardboard), and large aseptic dressing immobilized the limb. The prophylactic hemostasis was very complete and satisfactory. Before operating the limb was drained of blood by elevation, and an Esmarch constrictor was applied high up over the groin and held in place by a Wyeth pin inserted above the great trochanter. In this way the constrictor was held up very high in the hip and prevented from slipping. Notwithstanding complete hemostasis the shock was profound, and the pulse ran up to 160, and was very feeble (the duration of the operation had been over one hour and a half). Three quarts of saline solution were

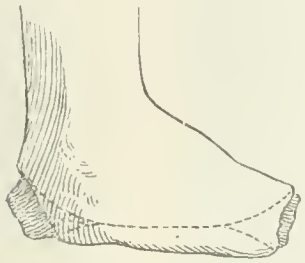
Fig. 3.

Photomicrograph of perineural fibroma of sciatic nerve. (Prepared by Dr. O. L. Polthier, Pathologist, Charity Hospital, New New Orleans, La.)

at once injected in the basilic vein, and the pulse fell to 120 and became full and strong.

A careful examination of the tumor was made by Dr. O. L. Pothier, Pathologist of the Charity Hospital, and many sections were cut from different portions of the growth. The bulk of the mass was found to consist "of a dense fibrous tissue of the adult type originating from the neurilemma of the sciatic and its branches." (See Fig. 3.) In many of the sections examined nerve-filaments were found very much distorted by a hypertrophic sclerogenic process, and totally surrounded by dense fibrous tissue.

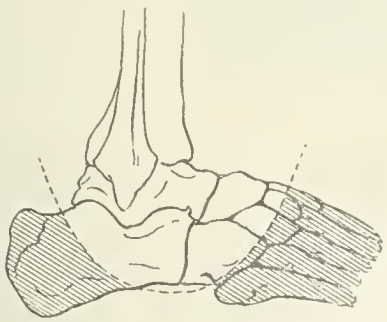
FIG. 4.



Here and there is the periphery of the growth, round, young, connective-tissue cells could be recognized in a state of transition to the adult forms. The growth of the fibroid tissue had been in many places interstitial, but the tendency of the fibroid process had been to grow excentrically and to invade the perineural connective tissue; this with the fascia and intermuscular septa soon participated in the process, and, in turn, attained huge proportions in consequence of progressive hyperplasia.

The next day the pulse stood at 140 and the temperature

FIG. 5.



103.5°. The foot, including the toes, could be moved freely by the patient, but all sensibility had left the toes and heel. The toes had also become markedly pale. Ecchymotic spots were noticed over the heel and in a small area over the tarsus. These spots, together with the toes, became subsequently the seat of a leathery odorless, dehydrating mortification. The general condition of the patient rapidly improved, and three weeks after the operation the sloughed parts were removed with scissors. No attempt was made to shape the stump. The heel and toe surfaces were gradually covered with indolent granulations, but the healing process was very slow. Coincidentally with this indolent effort at repair, signs of trophic and vascular disturbance (*viz.*, diminished sensibility, with redness and sweating in the sole of the foot, accompanied by "burning" pains in the plantar surfaces or "erythromelalgia") became pronounced, and annoying symptoms of neural lesion were unmistakable. Early in March, 1899, an atypical conservative operation was performed with the view of remodeling the stump and providing a suitable covering to the heel and toe regions. An external curvilinear incision was made on the dorsum of the foot, extending from the tendo-Achilles behind to the base of the metatarsals in front. (Fig. 4.) All the plantar structures were reflected in a single massive flap, including the vessel and nerves, from the skeleton of the foot, the bones of the tarsal being laid bare on the plantar surface. The skeleton of the foot was then reduced to the requisite size and shape by sawing the tuberosity of the calcaneum, part of the cuboid, and the cuneiform with the metatarsals. (The line of osseous section is indicated in Fig. 4.) In this way an ample covering of healthy plantar and dorsal flaps was obtained to cover the stump. In the course of this dissection the plantar nerves were exposed at their origin from the posterior tibial and stretched (as suggested by Chipault for the treatment of perforating trophic ulcer of the foot), hoping that by this procedure the erythromelalgia of the sole would be relieved. A very excellent, painless, and well-nourished stump resulted from this operation. The line of incision healed with remarkable rapidity and scarcely any suppuration. The vascular and neuralgic symptoms which had proved so annoying before the operation disappeared altogether, and the patient was soon able to leave the ward in excellent condition. He is now better than ever before, having gained remarkably in flesh and strength in consequence of his ability to enjoy outdoor exercise. When he last called to see me, in April, 1899, he was able to walk on the stump without pain or inconvenience, and had good normal motion at the ankle-joint. It is quite possible that with further exercise he may still have a recurrence of trophic symptoms in the foot, as the amputation is too recent to test the permanency of the recovery, but the result thus far obtained is certainly strikingly favorable and most encouraging. (Fig. 6.)

The points of interest presented by this case are:

1. The existence of a primary perineural fibroma originating in, and involving the entire sheath of the sciatic and its branches.

2. The diffusion of the fibroid process throughout the posterior aspect of the thigh and popliteal connective-tissue planes, without definite encapsulation, forming a hard, dense tumor of vast proportions.

3. The preservation of the entire sciatic nerve-trunk and its large popliteal divisions in spite of the intimate blending of the neoplastic tissue with the neurilemma which was incorporated in the tumor, and was completely surrounded by the mass throughout its course, more especially in the popliteal space.

4. The slow and painless growth of the tumor—ten years.

5. The involvement of the vascular sheaths of the popliteal blood-vessels in the tumor, which made it impossible to dissect the vessels out of the mass.

6. The extirpation of the tumor and excision of more than three inches (7.5 cm.) of the popliteal artery and vein.

7. The comparatively small area of popliteal sloughing (toes and heel) that followed the total excision of these vessels and many collateral branches.

8. The useful walking stump left to the patient, after a secondary partial and atypical amputation of the tarsus to remodel the stump.

9. The general good result as regards serious trophic lesions from injury to the sciatic nerve, which is an encouragement to conservative efforts in similar cases.

Appearance of the limb and cicatrix, showing the extent of the dissection required for the removal of fibroma of the sciatic. The appearance of the foot stump after healing is also shown.

MEDICAL PROGRESS.

The Dangers of Headache Powders.—SOBEL (*Med. Record*, Sept. 30, 1899) reports an instance in which a school teacher aged 25 years was severely poisoned by taking powders of a proprietary character which according to the label did "not contain morphine, opium, antipyrin or any other dangerous drug." The patient became very cyanotic and cold, with a pulse of 96 and a slightly subnormal temperature. She was given aromatic spirits of ammonia and strychnin and hot drinks, and in 24 hours the cyanosis had disappeared, and the pulse and temperature returned to the normal. Examination of the powders showed that they contained a large quantity of acetanilid. The writer expresses himself most strongly against the indiscriminate self-administration of headache remedies and says that the amount of the dangerous drug placed in one powder ought to be limited by law.

Failure of Operative Treatment of Abdominal Tuberculosis.—WUNDERLICH (*Archiv für Gyn.*, vol. 59, p. 216) reviews the dark side of laparotomy in the treatment of abdominal tuberculosis. So many instances have been reported in which complete recovery has followed simple abdominal section that one is apt to lose sight of the failures which result from this method of treatment. These failures are numerous, however. For example, during the last eighteen months Wunderlich had opportunity to observe ten patients upon whom abdominal incision was made. Of these ten, seven were in no way benefited and the process either continued undisturbed by the operation or the patient was directly injured by the same. In no instance was death directly due to the operation but in one the patient died within six days. The cicatrix under

went tuberculous degeneration with the formation of a fecal fistula. Altogether four of the patients died within three months in spite of the fact that two of them left the hospital in apparently perfect health. One patient who did not die suffered from a fecal fistula which formed n the scar within two weeks of the operation. These instances are sufficient to show that one may not speak of a cure of abdominal tuberculosis until several years have elapsed. Examination of hundreds of reported cases showed the writer that a recovery after abdominal section is most likely to occur in the ascitic form of the disease. In this form the patients who lived after the operation three years or more without a return of the symptoms numbered 23.3 per cent.; whereas only 9.8 per cent. of those who suffered from the adhesive form of the disease could be regarded as cured after abdominal incision. There is no doubt that the curative effect of laparotomy upon peritoneal tuberculosis is vastly overestimated. Indeed, one is almost justified in denying that laparotomy has any curative effect, since cases are recorded of spontaneous cure without any operation.

Increase in Weight of Infants Fed Artificially.—KOPLIK (*Arch. of Pediatrics*, Oct., 1899) says that infants fed artificially must not be expected to gain weight with the same regularity as do breast-fed infants. By a series of observations extending over nine years he found that when artificially fed infants are doing well they have a daily gain in weight ranging between twelve and thirty-two grams (half an once to one ounce). Most of the infants whose weights were taken lived in tenement-houses and many of them in distinctly bad hygienic surroundings. The fact that children under such circumstances often suffer from more or less severe attacks of indigestion would account for a part of the irregularity in their gain in weight. In private practice the figures are somewhat more uniform, but even then there is a great variation from week to week. Cammerer has shown that when infants are fed upon the breast there is an almost constant increase ranging between four hundred and six hundred grams (fifteen to twenty ounces) a month. Koplik brings out the interesting point that if an artificially fed infant is given the breast two or three times in the twenty-four hours or even only once during the twenty-four hours, it will show a much better average daily increase than a baby fed on the bottle alone. Thirteen babies who weights were tested daily under such circumstances closely approximated the figures given by Cammerer for exclusively breast-fed infants.

The "Rational" Treatment of Typhoid Fever.—PAGE (*St. Louis Med. Gaz.*, Oct., 1899) criticises the manner in which cold baths are used in the treatment of typhoid fever, saying that they should never be employed for the purpose of directly reducing the temperature but in order to remove the cause of fever and pain. This can never be accomplished by the use of antipyretic drugs. In addition to the cold baths of which the writer give sometimes as many as six the first day, the patient is kept on a strictly water-diet for several days until he is convalescent and actually hungry. During this time absolutely nothing is given but soft, fresh water in large quantities. In every case of extremely high temperature there is practically a loss of all the dissolving and preserving fluids, saliva, gastric juice, etc., and in place of digestion there is only fermentation and putrefaction of ingested food with consequent blood-poisoning. This is the explanation of the unsatisfactory results obtained by some physicians who have made use of the cold bath, the advantages of the bath in their hands having been overbalanced by the disadvantages of the food given as many physicians employ forced feeding as a routine practice. If no food is given it will not be necessary to continue the baths in most cases for more than a few days. Page gives the history of a patient, to whom six baths were given the first day, and two on the second day. It was not found necessary to give any baths after that, and in a week the patient was thoroughly convalescent.

A New Method of Reducing Dislocations of the Lower Jaw.—MCGRAW (*Med. Record*, Oct. 7, 1899) was called upon to treat a patient whose jaw had been dislocated by a fall in a paralytic stroke five months previous. The dislocation was bilateral. Protracted efforts to effect reduction under ether failed. A week later the patient was again etherized and a short incision under each zygoma was made. A small steel hook with a short prong bent so as to run parallel to its shaft was passed through the skin incision and the fibers of the masseter, and over the jaw-bone above the sigmoid notch, until the hook fastened around the neck of the jaw-bone in front of the condyle. Pieces of cork were then inserted between the molar teeth as far back as possible and an assistant pulled the jaw forward and upward with all of his force while McGraw made traction upon the hook. This was continued for fifteen minutes. The only results was to move the bone slightly. A similar operation was performed on the left side and the operator then succeeded in dragging the head of the bone back into its proper position. The incisions required were very short. Made in the proper place it is only necessary that each incision should be long enough to permit the entrance of the hook.

Dyce Duckworth on Bread-Making.—In a letter communicated to *Food and Sanitation*, this celebrated physician expresses his contempt for modern bread in the following manner:

"On my return to Scotland," he says, "I am always pained to find that the art of bread-making has much fallen below its former preeminence, and I am told that the public now clamours for raw, uncooked bread, and will have no other. Each time I come back to Campbelltown I have to educate my baker to prepare for my family bread properly fired, and I see that I get it. Not a loaf in any shop in the town would pass my inspection. The mischief which results from this uncooked bread is very serious. In this as in other cases, an ignorant public has its way, and the unwholesome demand is met by the supply of a half-cooked loaf. One result is plainly obvious, and that is the bad condition of the teeth of all

classes. With no hard crusts to chew, no vigor and health for the teeth, no adequate supply of saliva for digestive purposes, hence attendant degrees of indigestion. Artificial teeth, thus rendered necessary, of course increase the demand for raw crustless bread, and so all works in a vicious circle.

"It is surely sufficient to point out facts like these to intellegent Scotsmen and Scotswomen to secure a change for the better, and to enable the bakers to practise their business as they well know how. Extra firing till the crust of the loaves is almost brown, and three-sixteenths of an inch thick, is what is requisite. This is no 'fad,' or matter of fashion, but a necessity for all time."

THERAPEUTIC NOTES.

Treatment of Malaria by Inunction of Creosote.—FITZGERALD (*Brit. Med. Jour.*, July 15, 1899) has treated a number of patients with a mixture of creosote and olive-oil, 1 part of the former to 3 of the latter, using from 15 to 20 minims of creosote for a child and 30 to 60 for an adult. The results were remarkably uniform. In the patients who had already been treated with quinin, there was an immediate improvement and no relapse, but owing to the previous treatment the creosote could only be looked upon as an adjuvant to the quinin. In another class of cases consisting of adults to whom quinin had not been administered recovery was equally prompt. The temperature became normal in a few hours and remained so and there were no relapses. In most instances only one application of the creosote was made. In a third class of cases consisting of children some of whom had previously received quinin, the effect was even more striking than in the case of adults. For instance, a child aged three and a half years had a temperature of 105 4° F. taken in the groin at 11 P. M. For two days she had had a high fever and would take no medicine. She was quite delirious. Twenty minims of creosote were rubbed in at once, and the effect was almost instantaneous. The delirium ceased rapidly, consciousness returned, there was great irritability for a few minutes and then the patient became quiet and soon fell into a sound sleep lasting two hours. In half an hour from the administration of the creosote the temperature had fallen three degrees. At seven o'clock the next morning it was 100° F.; at ten o'clock it had risen again to 105° F. and convulsions were beginning. Twenty minims of creosote were again rubbed into the skin and immediate relief again followed. This treatment was repeated five or six times in the course of the next twenty-four hours. The following day the temperature was normal and remained so. The writer looks upon this treatment of malaria in children as ideal. Even in very severe cases it acts rapidly and continuously and, as far as he has observed, with absolute certainty. No bad effects have been noticed as a result of excessive use of the drug.

An Effective Treatment of Vesical Hemorrhage Due to Papillomatous Growths.—HERRING (*Brit. Med. Jour.*, July 29, 1899) says that if a patient is suffering from vesical hemorrhage due to papillomatous growths a diagnosis can usually be made by washing out the bladder with sterile water and at once mounting the shreds of débris for microscopical investigation. If the diagnosis is a positive one the daily injection of solutions of nitrate of silver will suffice to control the hematuria and in some instances may completely cure the condition. Four ounces of warm water containing one-half grain of the nitrate suffice for the first injection. The strength should be increased every day or two until the four ounces contain one and one half or possibly two grains. The susceptibility of the patient's bladder should be the guide. He ought never to feel pain but only a warmth in the vesical region which should subside entirely in half an hour. The solution should not be so strong as to cause frequency of micturition. When the maximum strength has been determined the irrigations should be continued daily for a few weeks. If bleeding has then ceased the patient may use the injections every other day for six months, and after that every third day for a variable period. Finally, treatment may be abandoned but should immediately be resumed if hemorrhage recurs. It is needless to add that strict asepsis should be observed in these cases as a septic cystitis in a patient with papillomata of the bladder is a most troublesome condition.

A Dental Hemostatic.—Mix 2 parts chloroform with 100 parts water. Use after extraction of teeth.—*Spaak.*

For Hemoptysis —

℞ Ext. hydrastis fl. } aa. . . . ℥ ss.
Tinct. hydrastis. }
M. Sig. Twenty to 50 drops three times a day.

In addition to its hemostatic action, the above has a good effect on appetite and digestion and never nauseates. In case of obstinate cough the addition of codein or morphin is recommended as follows:

1. ℞ Ext. hydrastis fl. } aa. . . ℥ ss
Tinct. hydrastis. }
Codeinæ . . . . gr. v–viii.
M. Sig. Twenty to 50 drops three times a day.

2. Ext. hydrastis fl. } aa. . . ℥ ss
Tinct. hydrastic }
Morph. hydrochlor. . . gr. iiss–v.
M. Sig. As above.

The treatment should be continued for several days after the hemoptysis is arrested, and the dose then be rapidly diminished. It is important that the preparations used should be fresh.—*Scarpa.*

Elimination of Toxins by Means of Salivation.—LEUBE of Wurzburg, having observed a case of ascites which was relieved by a copious flow of the saliva, tried the effect of salivation in a number of cases of effusion (pleuritic and ascitic), and found that resorption of the fluid began immediately after the treatment, which consisted in the use of chewing-gum, was instituted. He considers that while the kidneys and skin are taxed to the utmost in the effort to cause the elimination of poisons, the salivary glands are usually overlooked, and suggests that salivation should be tried in addition to diuresis and diaphoresis in the treatment of hydrophobia.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

J. RIDDLE GOFFE, Ph.M., M.D., Editor,
No. 111 FIFTH AVENUE, NEW YORK.

SATURDAY, DECEMBER 9, 1899.

HOW TO QUARANTINE AGAINST THE PLAGUE.

THE recent appearance at Quarantine in New York harbor of a ship hailing from Santos, Brazil, laden with coffee, and having on board two cases of bubonic plague, has raised the question in a most practical way as to what quarantine requirements are necessary to allow the ship pratique. The two patients were placed in the quarantine hospital and the rest of the crew in detention-quarters for disinfection and observation; the ship was thoroughly disinfected, and the coffee placed in bulk on lighters and exposed to the air for eight days. Quarantine Officer Doty considered these sanitary measures sufficient to obviate all danger of infection and passed the ship and cargo through quarantine.

The New York City Board of Health, however, insists that there is at present no known method of disinfection that will guarantee immunity in such circumstances; has notified the consignees of the ship that the vessel cannot come to any dock in the city, that it cannot pass by the city, and that the coffee cannot be landed even from the lighters. In order to insure the execution of these orders, the police patrol boat has been placed on guard to watch the lighters and the ship. To add to the complication two other ships have arrived from Santos, loaded with coffee. It is also reported that ten more coffee laden ships are now on their way to New York from the plague tainted port of Santos.

The success that has been attained at Singapore in preventing the entrance of plague into that port, and the quarantine measures that have been applied in accomplishing this end, may throw some light upon the question at issue. The *British Medical Journal* of November 25th in speaking of this says: "A very remarkable feature of the plague in the East is the immunity which Singapore has enjoyed, notwithstanding its communication with infected ports."

The system adopted for dealing with ships arriving from infected ports was to anchor them at the quarantine station, where the passengers and crew were inspected by the Health Officer, after which the passengers were landed at an island, and there detained until nine days had elapsed from the time they left the infected port. The ship was disinfected if necessary, and allowed pratique. Not only was this inspection duty of a very onerous nature but the opportunities for bringing infection were very great. Vessels from China at times brought from 3000 to 4000 coolies, each of whom had to be personally examined before being permitted to land, and attempts at concealment of illness were frequent. The numbers inspected were—in 1895, 195,633 passengers and 11,438 crew; in 1896, 145,814 passengers and 43,457 crew; in 1897, 115,542 passengers, and 12,573 crew; and in 1898, 144,686 passengers and 12,571 crew. In each year a number of plague cases were detected and isolated, and in the first seven months of 1899 ten such cases were dealt with in addition to five that were doubtful.

"The experience of the five years," says our authority, "showed that the risk of plague infection from certain cargoes coming under the category of susceptible is practically *nil*, for owing to the vast amount of commercial business done at the large ports of Hong Kong and Singapore, no disinfection of cargo was attempted; yet no case of plague occurred in Singapore from the admission of susceptible cargo, or from its being unpacked, packed, or handled."

This experience at Singapore provided the *British Medical Journal* is in possession of all the facts seems to justify Health Officer Doty in the position he has taken. The journal, however, does not affirm that there have been no cases of plague in Singapore but that "no case occurred there from the admission of susceptible cargo." If cases have existed there as reports show they have, it might be difficult to establish the statement that none of them came from any of the "susceptible" cargoes. The condition at New York is too serious a matter for the application of any experiments and until safety is established beyond peradventure of a doubt it is well to wait.

THE GENESIS OF THE ALBUMINS IN ALBUMINURIA.

WITHIN recent times it has become a fact of general recognition that the urine of patients suffering from albuminuria contains more than one variety of albumin, and extended research has shown that at least three albumin compounds are to be borne in mind. These most important bodies are serum albumin, serum globulin, and nucleo-albumin. With the definite appreciation of what these bodies are, the further knowledge of where they come from is, however, not so clear; and what the functional changes in the kidneys may be, which are correllated with the chemical variations of its secretions, is a subject that has invited much speculation as well as experimental investigation, with as yet but contradictory results. Such is not to be unexpected when fully acquainted with the intricacies of the question involved, as Senator's monograph on diseases of the kidney evidences.

With the determination to ascertain, if possible, the causes for the elimination of each of these bodies, M. Cloetta of the University of Zurich (*Arch. für Pathologie und Pharmakologie*, 42, 1899, p. 452) contributes a series of clinical observations, experiments, and pathological studies. Albumoses, peptones and other well-recognized constituents are not included in the general discussion since their pathogeny is fairly well established.

The methods of experimentation employed were various but most of them depended on the relationship of the bodies found in the blood and in the urine following some definite method of kidney irritation. Experiments making use of osmolytic phenomena were also freely employed. These latter seemed to show that the character of the transfused albumin depended in large part on the thickness and permeability of the osmotic membrane, and thus pointed directly to the suggestion that in the kidneys themselves, the thinner the epithelial layers, the transudate more closely resembles the composition of the incoming fluid, *i. e.*, the blood in certain of its albumin constitutents. The thicker membranes render the passage of globulins more difficult. When, with this result is borne in mind the clinical experience, that in acute nephritis the serum globulin is quite appreciable, and that on the other hand the serum albumin quotient is much higher in chronic contracted kidney, and that as recovery gradually takes place in acute nephritis the serum albumin increases, it may be seen that some correllation may be made between clinical and experimental results. Irritation of the kidney substance by means of injections of aloin, in guinea-pigs, has also brought about suggestive results.

With reference to the presence of nucleo-albumin the author is of the opinion that it comes not so much from the blood-current as from the renal epithelium itself. Thus in the acute degenerative types of nephritis it is nearly always present and comes from the degenerated cells of the tubules; in chronic indurative cases it is found in small quantities only. In cases of eclampsia it is also absent, whereas in the nephritis of the acute infectious diseases nucleo albumin is found in large quantities. It thus serves as an index of the amount of cellular degeneration in the renal structures.

THE RAILROAD SURGEON AS A FACTOR IN MODERN LIFE.

THE recent meeting of the New York State Association of Railway Surgeons, a brief account of which appears in our columns this week, calls attention once more to the duties that railways owe to their patrons in the matter of prompt, efficient, and expert medical and surgical assistance in case of accident. Important railroads entering New York City, following a lamentably shortsighted policy, have no organized corps of surgeons ready to answer their emergency calls. A certain number of accidents on railroads are practically inevitable. To save suffering and the serious consequences that may

result from delay in treatment or unskilled first aid to the injured is evidently an important duty of the railroad company. This should be insisted on by patrons of these dilatory lines.

The question of the physical fitness of railroad employees is of great interest and importance. So much depends on the eye or the ear of the railroad employee that it is important that these organs should be tested carefully on entrance into the service and continuous supervision be exercised at stated intervals. Where large numbers of men are employed occasional examination by a neurologist would also seem to be demanded in the interests of both the company and the traveling public. This may seem a refinement to those who have not considered the subject, but it has been known more than once that men liable to occasional attacks of epilepsy have held the position of switchman or signalman, and it is to this that accidents may occasionally be undoubtedly attributed. Epilepsy, as is well known, develops in some instances late in life, and gives no warning of its approach except to the skilled specialist. There are, moreover, the various forms of mental aberration, whose fatal consequences can only be anticipated in the same way.

During the past year a number of the English, French, and German railroads, following the example set by certain progressive American lines, whose surgeons first saw the usefulness of it, have equipped their cars with first-aid packets, practically the same surgical dressings as are supplied to soldiers in the field. Employees are being drilled in the simple principles of first aid to the injured. If this should have no other result than to prevent the meddlesome interference that so often does harm every surgeon will readily appreciate its possibilities for usefulness.

We have entered upon a phase of modern life when every detail that foresight can provide to lessen danger and decrease human suffering is welcome as part of the great modern advance in humanitarianism.

These details of medical service may seem trivial in comparison with other great interests and the fortunately rare necessity for their application in our day may lead to their neglect, but the duty in the matter is plain.

Cadiz Infected.—It is reported that one bona-fide case of bubonic plague has developed at this place.

ECHOES AND NEWS.

Professor Lenhossek of Tubingen has been called to occupy the professorship of anatomy in the University of Budapest.

Dr. Born Elected Professor of Diseases of the Eye at the New York Polyclinic.—At the last meeting of the Faculty R. O. Born, M.D. was unanimously elected to the professorship of ophthalmology.

Smallpox at Ohio Wesleyan University.—A student in the Girl's Seminary of the Ohio Wesleyan University, at Delaware, O., was taken ill with smallpox November 28th, and, immediately her disease was made known, 225 of the 300 students attending scattered for home.

Western Doctors Will Go To Paris.— It is reported that more than four hundred physicians from Illinois, Iowa, and Missouri are arranging to sail from New York on the "City of Rome" June 30, 1899. Their main object is to attend the International Congress of medical men to be held in Paris during the exposition.

State Sanatorium for Consumptives.—The Committee on Sanitation of the New York State Board of Charities held a meeting at Rochester, December 2d, to outline a bill for the establishment of a sanatorium for consumptives in the Adirondacks. The committee will report in favor of the sanatorium, at the meeting of the State Board in New York on December 12th.

Serum Treatment of the Plague.—The serum of Yerzin, obtained from the Paris Pasteur Institute, is being employed at Santos for the treatment of the plague. Thus far 800 grams have been used, but with little success. It is believed by the authorities that the serum is inefficacious because of its age, a factor that Koch has shown to be a very important one. Experiments with fresh serum at Oporto has given most satisfactory results.

Testing a Cure for Leprosy.—Experiments are to be made at Honolulu in the use of a Venezuelan shrub for the treatment of leprosy. The samples have been forwarded by Surgeon-General Wyman of the United States. The shrubs are growing at Honolulu under the care of Dr. Carmichael of the United States Marine Hospital Service, who has been asked by the department at Washington to make the experiments.

Sale of Quinin in Batavia.—A report from the United States Consul at Batavia, Java, under date of October 14th, relates the results of efforts to arrange for the sale, independently of the trust in Europe, of the quinin product of the Java cinchona-bark plantations. The first public auction will take place in Batavia about the end of January, or in February next. Some 7000 kilograms of sulphate of quinin will be sold. The Consul advises American firms to take advantage of this opportunity.

Oysters and Hospital Drainage.—Residents of Suffolk County have complained to the State Board of Health

that the Long Island State Hospital empties its drainage into the Nissequogue River which passes out over oyster and clam beds in the Sound. In the event of typhoid fever occurring in the hospital this drainage would undoubtedly contaminate the oysters. Dr. Baxter T. Smelzer, secretary of the State Board of Health, and State Engineer Bond have been sent to investigate.

Professor Sanarelli on Yellow Fever Once More. — The distinguished discoverer of the bacillus icteroides has sent us an answer to the recent criticism of his position as regards the specific pathogeneity of that bacillus for yellow fever which have appeared in the columns of the MEDICAL NEWS. His answer will be found to be a very good review of the present position of the subject with a very sharp and somewhat personal retort upon his critics. Surgeon-General Sternberg contributes a dignified response.

Our "Strenuous" Governor.—Governor Roosevelt, who has from time to time urged his fellow-citizens to lead a "strenuous" life, is putting his theories into practice. The spacious billiard-room of the Executive Mansion at Albany has been transformed into a gymnasium and a course in wrestling has been begun. At the first lesson it is said that the Governor, in ring costume, was so vigorous in his exercise that his instructor was in constant danger of being rendered *hors de combat*. At this rate a number of physical culture gentlemen will have to be provided for the season.

A Pharmacist Punished for Substitution.—In a bill for an injunction Fairchild Brothers & Foster of New York had charged Edward Otto, a Chicago druggist, with substituting a spurious and inferior preparation for "Fairchild's Essence of Pepsin" in several cases where the latter was expressly called for in physicians' prescriptions. The case was hotly contested and hundreds of pages of depositions were taken in New York and Chicago. Judge Kohlsaat's decree sustained the charges made. It perpetually enjoins Otto from ever repeating the offense and taxes him with the costs, amounting to about $500. Judge Kohlsaat's decision will probably protect manufacturing chemists, physicians and the general public, all of whom have in the past suffered from these fraudulent practises of a certain class of druggists.

Obituary.—Dr. Sheffield Green died November 29th, at his home in Richberg, New York, aged eighty-seven years. He served as surgeon in the Civil War and during the Appomattox campaign he was acting surgeon of the One Hundred and Forty-seventh New York Infantry. —Dr. John Stamford Sayre, formerly Passed Assistant-Surgeon in the United States Navy, died at his home in Monticello, Missouri, on November 30th. He was a graduate of Princeton and of the Medical School of the University of Michigan.—Dr. Charles Edmund Jones, son of the late Dr. Erasmus Jones, died on December 1st. He studied medicine at the Albany Medical College after which he took a course in the Homeopathic Medical College in New York. He had been president and secretary of the Albany County Medical Society and has been a member of several homeopathic organizations.

Inoculation against the Plague in India.—Lord Curzon, the Viceroy of India, at a recent meeting at Poona, expressed himself vigorously in favor of inoculation against the plague, and gave proof of his faith by submitting to the operation himself. Although the Viceroy is a layman his opinion is nevertheless of interest. He observes that out of 100 plague seizures among uninoculated persons, the average number of deaths is about 70 to 80 per cent., while in a corresponding number of cases among inoculated persons the proportions are entirely reversed, and 70 to 80 per cent., if not more, are saved. He considers that such figures cannot fail to carry conviction and he does not see how, in the face of them, it is possible for any one to doubt the value of the process. The majority of the most distinguished native medical practitioners in the country are already in its favor, and more and more converts are being made from the remainder each day.

Sanitary Condition of Santos. — In view of the extension of the plague at Santos it is of interest to know of the sanitary conditions there existing. The reports that can be relied upon describe the town as in a very filthy condition. By reason of there being an epidemic of yellow fever there some attempts have been made to clean up the sewerless streets, but thus far the attempts have been ineffectual. The dock commissioners report a very great increase in the number of dead rats. This from the known association of rats and the plague has caused some anxiety, which should call out active methods for the cleaning of the city. Disinfection of departing cargoes is not carried on nor is the property of emigrating persons subjected to any thorough disinfection. Though the health authorities are being stirred to activity, they do not possess the necessary corps of equipped sanitarians nor the apparatus.

Sidelights on the Plague —The steady persistence of the plague at Oporto is still watched with some uneasiness. Two hundred and thirty-six cases in nearly twelve weeks is not an appalling epidemic, and the death-rate is barely 30 per cent., but the profession is both grieved and alarmed by the lamentable death of one of its own members, Dr. Pestala, the Director of the Bacteriological Institute at Lisbon, as a result of an infection contracted while investigating the plague at Oporto. Nearly sixty persons who were unfortunately inmates of the same house with the doctor had to be taken to the lazzaretto, and the town was naturally a good deal alarmed, but fortunately no new cases have been reported in the four or five days since. As an ingenious amplification of Dr. Patrick Manson's campaign against the plague may be mentioned the procedure of the French sanitary authorities in Algiers, who, after carefully sealing all openings in the sewers and flushing all traps, proceeded to charge them with large quantities of sulphurous acid gas. In this way they succeeded in suffocating, in their inmost fortress and chief resort, the rats with which the town was infested. What a price, by the way, the Pied Piper

of Hamlin could command from plague-threatened municipalities, if he could only reappear in these days.

Dr. William H. Welch to Be Honored by His Pupils.—It is customary in Germany for the pupils of a great teacher to express their appreciation and gratitude by dedicating to him a volume of their contributions to learning. The pupils of Dr. William H. Welch of Baltimore have decided to give expression to their regard for him in a similar way and the publication of a volume to mark his twenty-fifth year as a teacher and investigator is now in progress. During the past twenty-five years some seventy-five persons have undertaken investigation under Dr. Welch s leadership and nearly half of these will contribute to the volume mentioned. The edition will necessarily be limited by the number of subscribers. An early announcement of the publication is made to give opportunity for subscription, so that the committee can decide upon the number of copies to be printed. The volume will be royal octavo in size, and will contain at least five hundred pages of printed matter. It will be illustrated with many lithographic plates and text figures. The price has been fixed at five dollars. The book will contain contributions to pathology and to correlated sciences agreeing in scope with that of the leading scientific journals. All communications and subscriptions should be addressed to Dr. F. P. Mall (Secretary of the Committee of Publication), Johns Hopkins University, Baltimore, Md.

Health of Our Troops in the Philippines.—When the Philippine War, now apparently drawing to a close, shall be ended not the least of its many unusual features will be the exceptionally low death-rate of the American Army, including in this view both the mortality on the field and the mortality from disease. If any Volunteer regiment afforded a good test of comparison it was the fighting 20th Kansas. With a roll of 46 officers and 1266 enlisted men, after months of the most active and courageous service, it recorded a loss of only 3 officers and 30 enlisted men killed or dying of wounds. Only 33 Kansans died of disease, the total death-rate being only 5 per cent. for the men and 6 per cent. for the officers, all of whom were exposed to the double danger of an enemy's bullets and a tropical climate. We all remember the dire predictions of a year ago as to the terrible ravages in store for our troops when they came under the burning skies of Luzon. They were to go down by the thousands and not even our best medical arrangements were counted on to do more than slightly mitigate the effect of the inevitable calamity impending. General Otis has had practically a city of 30,000 inhabitants under his command in the soldiers serving under him, yet if the same record of mortality were made in any American city of the same population there would be no alarm expressed nor would the place be avoided as being especially unhealthful. —*Army and Navy Journal.*

Notes on Santos.—Santos is a small city, some three hundred miles south of Rio de Janeiro. The population of the city is made up largely of laborers dependent upon the coffee interests for their living, the better merchants of the place residing in the city of Sao Paulo, the capital of the State, thirty miles inland. The importance of the place in the world's commerce may be appreciated from the fact that in 1891 the total shipping amount to 808,000 tons. The city is very flat and most of it is but a few feet above sea level. As a result it is surrounded by large areas of fresh-water swamps, because the heavy surf from the ocean throws up a dike of sand along the sea front, thus holding back the waters of the streams from the mountains, except in times of very heavy rains, when the large flows break through and for a time relieve the swamps of their surplus water. The town has a system of sewers, but they are laid on very flat grades and in some cases have no slope, the putrefying sewage filling long lines of mains and giving off offensive odors, as well as infecting the subsoil. The sewage is collected at a pumping station at the edge of the town and discharged into the harbor on the mud flats, a pretense of chemical treatment being made in some small settling basins. The works as administered are thoroughly insufficient, and it is evident that, in view of their imperfect construction and inadequate sizes, they will have to be reconstructed, especially as the point of discharge of the effluent is in a very unfavorable place, and as there is a good location for it a little further down stream. There are also a number of drains, with walls laid without mortar, leading under the business portions of the town, running under the buildings and almost impossible to trace. The filth in these is carried back and forth by the tides and their embouchures are into the harbor, through the walls upon which the vessels discharge their cargoes. In the central portion of the business district there is a depression of the grade of the street, thus forming a pocket in which the surface water collects during heavy rains on account of the stoppage of an untraceable drain, and the store proprietors in the region built masonry dams about three feet high across the doorways to prevent this flood entering the stores and ruining their stocks. The houses are built in the manner characteristic of the country, being generally one story in height, of masonry, and with no cellars or ventilation under the floors, with no windows in the interior rooms, and with the most primitive sanitary arrangements. The streets and yards of houses are often in a most filthy condition, and personal habits of cleanliness and decency are on every hand observed to be violated to a disgusting degree. On the sidewalks of the side streets, in the heart of the town, deposits of fecal matter are frequently observed, and the drains from the urinals, located often against the fronts of houses, commonly discharge their contents in the street gutters. An effort was made by the city authorities to mitigate the evil by disinfecting these places with chlorid of lime, but various distinctive odors on a hot moist day are in strong evidence all over the town. In view of the fact that plague has now invaded this unfortunate country, it is to be regretted that the sanitary conditions are so bad. Once more the customary salutation of the nightly parting of friends in business will be "good bye" instead of "good-night."—"Marine Hospital Report."

MEDICAL MATTERS IN NEW YORK.

YELLOW FEVER ON A TRANSPORT—HOSPITAL SERVICE IN QUEENS—IMPROVEMENTS AT ST. VINCENT'S HOSPITAL—SMALLPOX AT FORT SLOCUM—MATERNITY HOSPITAL WORK—THE CITY BUDGET.

THE transport "Burnside," which arrived at Quarantine on November 28th from Havana, had one case of yellow fever aboard, a discharged soldier of the United States Hospital Corps. He was removed to Swinburne Island and the ship was held for disinfection.

There is much complaint in the Borough of Queens of the insufficient hospital and ambulance service. The Jamaica Hospital refuses to attend cases beyond a radius of two miles from the hospital, and will not attend to medical cases without a physician's certificate. The hospital receives from the city the munificent appropriation of $1500 a year; this amount, however, it considers inadequate.

The fiftieth anniversary of the founding of St. Vincent's Hospital was celebrated on November 26th by the dedication of the new chapel by Archbishop Corrigan. This chapel is of French Renaissance design. All of the fittings and furnishings are gifts from friends of the hospital. A children's ward, for children of both sexes over two years' old, and a free dispensary have also been opened.

Two cases of smallpox were discovered at Fort Slocum on Daniel's Island near New Rochelle on November 27th. The patients are two soldiers who came from Birmingham, Ala., ten days before the above date. Dr. Peck of New Rochelle investigated the situation and considered that there was no danger for that city but a quarantine was established against Daniel's Island.

An outline of the work of the Society of the Lying-in Hospital during the last seven years is contained in the advanced sheets of the annual report. The recent enlargement of its equipment through the liberality of Mr. J. Pierpont Morgan is described. Property adjoining the hospital has been secured which makes available for the new structure a total space of 21,750 square feet. The new building is expected to be ready for use on January 1, 1901.

Controller Coler's recent investigation into the appropriation of municipal funds for charities is discussed in the report. The recommendation made by the Controller's investigating committee, that the further granting of public funds to charities in this city be discontinued, is condemned. Since 1896, $12,000 has been received annually by the society from the city.

According to a decision rendered some time ago by Justice Pryor, ambulances taking people to hospitals have no absolute right of way, but must take their turn in the streets like other vehicles. In consequence, Commissioner Keller has notified drivers that they will make themselves personally responsible by getting into street accidents through hurry. It is hoped that this rule may curb somewhat the officiousness of the ambulance surgeons and drivers.

The budget of Greater New York for municipal government in 1900 will be about $79,202,000—a net total decrease of about $4,500,000. Instead of the appropriations for 1899, of $1,941,215 for the Department of Public Charities and of $1,784,847 for charitable institutions, those for 1900 are respectively, $1,696,813 and $2,857,084.

The Health Department submits the following report of contagious diseases for the week ending December 2, 1899: measles, 275 cases, and 11 deaths; diphtheria, 260 cases, and 41 deaths; laryngeal diphtheria (croup), 7 cases, and 13 deaths; scarlet fever, 149 cases, and 7 deaths; smallpox, 2 cases; chicken-pox, 21 cases; tuberculosis, 199 cases, and 134 deaths; typhoid fever, 53 cases, and 19 deaths; cerebrospinal meningitis, 3 deaths.

MEDICAL MATTERS IN PHILADELPHIA.

[From Our Special Correspondent.]

PROPOSED NEW JEWISH HOSPITAL—GIFT OF $250,000 TO THE UNIVERSITY OF PENNSYLVANIA—PRESBYTERIAN HOSPITAL IMPROVEMENTS—MEDICAL CLUB OF PHILADELPHIA—BEQUEST TO THE MUTUAL-AID ASSOCIATION—DEATHS AND INFECTIOUS DISEASES DURING THE CURRENT WEEK.

PHILADELPHIA, December 2, 1899.

THE new Beth Israel Hospital, if, indeed, this institution ever arrives at the dignity of its charterhood, is passing just at present through a turbulent stage of its early infancy. This is due to certain manifestations of the traditional trilogy of envy, hatred, and malice evinced toward the new project by numerous groups of downtown Jewish doctors not included in its list of proposed medical officers The projected hospital is the outcome of a movement recently instituted by the Jewish residents of the southern section of this city to establish a hospital downtown for the benefit of orthodox members of their faith; but, owing, it is said, to factional feelings arising among a large number of Jewish doctors who have been disappointed in seeking positions in the new institution, there is a probability that two, not one, new Jewish hospitals will be established in the near future. The Beth Israel Hospital had obtained a list of 500 pledged subscribers, assuring it an annual income of at least $5000, and includes in its medical staff the names of some of the most prominent Jewish physicians practising in this city. Its rival, as yet unnamed and unendowed, is pursuing a hot chase in quest of funds and of backing, and purposes choosing its medical officers from those Jewish doctors disbarred from holding positions in the rival institution by a clause in the latter's proposed charter declaring that no resident or visiting physician shall be eligible for appointment unless he is a medical graduate of ten-year's experience. Meanwhile, the original Jewish Hospital, long established in the northern part of town, calmly continues its work, and, glancing at its record of an annual deficiency of $5000 or $6000, wonders where a valid excuse for the multiplication of similar institutions is found.

Provost Harrison has announced that a gift of $250,000 has been made to the University of Pennsylvania for the establishment of a new Laboratory of Physics, the donor being a public-spirited Philadelphian who desires that for the present his name be withheld from the pub-

lic. For some time the authorities of the university have been engaged in studying similar laboratories in both this country and in Europe so that within a short time it is hoped that the plans for the new structure and all its detailed equipment will be prepared, making possible its early erection.

The James Hogg Memorial Home for Nurses of the Presbyterian Hospital was formally dedicated, with appropriate ceremonies, on the evening of November 28th. The new building is the gift of J. Renwick Hogg, and with its completion another fine structure has been added to the already notably well-equipped group of buildings owned by this institution. The new building is constructed of brick and stone, in the Renaissance style of architecture, being three stories in height, and having accommodations for 68 nurses. The Neurological Ward of the hospital, now nearing completion, will furnish accommodations for 28 patients; it will be under the special supervision of Drs. S. Weir Mitchell, John K. Mitchell and Guy Hinsdale.

The Medical Club of Philadelphia, which comprises among its members about 500 physicians of the regular school, is about to become an incorporated organization, and to acquire a property for club purposes, situated in a central neighborhood. The recently elected officers of the club are as follows: President, Dr. James M. Anders; Vice-Presidents, Drs. Charles W. Burr, and G. E. de Schweinitz; Secretary, Dr. Guy Hinsdale; Treasurer, Dr. John H. Locke. The Governors of the club are Drs. A. H. Hulshizer and Charles K. Mills.

The will of Dr. Albert Fricke, who died last week, bequeaths one-half of his residuary estate to the Mutual Aid Association of the Philadelphia County Medical Society. The estate is valued approximately at $33,000.

The total number of deaths in this city for the current week was 410, or an increase of 34 over the number reported last week, and of 11 for the corresponding week last year. There were 142 new cases of diphtheria, with 31 deaths; 54 new cases of scarlet fever, with a single death; and 35 new cases of enteric fever, with 6 deaths.

CORRESPONDENCE.

SURGEON-GENERAL STERNBERG'S REPLY TO SANARELLI.

To the Editor of the MEDICAL NEWS.

SIR:—Accept my thanks for the opportunity to read proof-sheets of Dr. Sanarelli's last article.

I gave some of my reasons in my article published in the MEDICAL NEWS of August 19, 1899, for maintaining a position of scientific conservatism as regards the etiological rôle of Sanarelli's bacillus. The paper which you are about to publish adds nothing to the experimental data previously recorded, and, as I said in my paper above referred to, "I have no time or inclination for controversial writing." I have been unable to make any personal investigations since I was appointed Surgeon-General of the Army in 1893, but have followed with deep interest the researches of other investigators, and when the evidence is all in hope to arrive at an unbiased opinion with reference to this important question. For the present I see no good reason for changing the opinion expressed at the conclusion of my previous communication, *viz.*, that the etiological relation of Sanarelli's bacillus has not yet been established. But, as I said in conclusion, "If, however, the results reported by Drs. Reed and Carroll can be shown to be based upon erroneous observations, I shall be ready to revise my opinion. Truth is mighty, and no doubt in the end will prevail."

Dr. Sanarelli's supposition that Drs. Reed and Carroll have been "working with a bacillus which is not bacillus icteroides" is without foundation. The statement made by Reed and Carroll in their paper published in the MEDICAL NEWS of September 9, 1899, is entirely correct. This is as follows:

"In the first place, before proceeding to consider Sanarelli's criticisms of our work, we desire to state that the culture of bacillus icteroides with which we have made the majority of our observations, was obtained by Dr. Sternberg from Pasteur's laboratory. We are informed by Dr. Sternberg that the package containing this culture was opened by Professor Roux in his (Sternberg's) presence, and the culture handed to the latter. It was delivered to one of us by Dr. Sternberg on September 24, 1897, and bore the label of the Laboratory of Hygiene, University of Montevideo. We may remark that this culture was not in the shape of the ordinary stroke culture, but contained a number of well-isolated colonies, such as would be obtained by inoculating an agar slant with a small drop of the blood of an infected animal. Several of the colonies on this agar slant showed the peculiar appearance of growth which Sanarelli considers as characteristic of bacillus icteroides. It was from one of these so-called characteristic colonies that we made our first transfer. Subsequent transplantations have been made by us at intervals of about four weeks, and have always been labeled 'Bacillus Icteroides, Original.' We have thus transplanted this original culture on agar, without transmission through animals, for a period of nearly two years. Like our other stock cultures it has been kept in agar tubes provided with rubber caps, and always in a dark closet.

"In the second place, at the time we began our investigations (September, 1897), no culture of the hog-cholera bacillus was in our laboratory, nor did we procure a culture of this bacillus from the Bureau of Animal Industry until the following spring (May, 1898), about seven months after we had begun our work."

I expect soon to receive a full report of the researches made by Drs. Reed and Carroll at the Army Medical Museum, and also those made by Dr. Agramonte in the City of Havana during the past summer. At some future time, when the experimental evidence is all before us, I hope to make a critical review of the subject of yellow-fever etiology, and if I arrive at the conclusion that the question has been definitely settled I shall be greatly pleased, for I am deeply interested in the advancement of scientific medicine. But the progress of science, in the past, has often been retarded by premature announce-

ments of discoveries, and by confirmation of alleged discoveries by prejudiced or incompetent investigators. A spirit of scientific conservatism is, therefore, very desirable if one would judge for himself of the merits of a question which can only be decided upon experimental evidence.

Very truly yours,

GEORGE M. STERNBERG,

Surgeon-General, United States Army.

WASHINGTON, D. C., December 2, 1899.

OUR LONDON LETTER.

SANITARY DRAWBACKS AT LADYSMITH AS A CAMP-SITE—DYSENTERY DUE TO DUST—HOSPITAL SHIPS AND TRAINS—MILITARY SANATORIUM AT WYNBERG AMONG THE PINES—THE "MERCIFUL MAUSER" AGAIN—HOSPITAL SHIP OF AMERICAN LADIES ALMOST READY TO SAIL—ENTHUSIASTIC STUDENTS—OVATION TO MR. TREVES—DEATH FROM ANTHRAX IN A HAIR-CURLER—APPROACHING "BACK-DOWN" OF THE LEICESTER BOARD OF GUARDIANS—THE HUMANITY OF MEDICINE, AN AMBULANCE FOR THE BOER WOUNDED—ANOTHER DETERMINED MOVE FOR WELSH WATER. A ROYAL COMMISSION AS A "SHELF"—SEIZURE OF EGGS "FOR ELECTION PURPOSES."

LONDON, NOVEMBER 25, 1899.

THE reports from the seat of war as to the thoroughness and practical working of the medical arrangements continue to be most satisfactory, although there are vague rumors of a shortage in the medical corps of some of the last bodies of troops sent out. There appears to be comparatively little sickness among the troops, although now that the letters from the war correspondents of the various journals, which have not, like their telegrams, passed under the censor's rigorous eye, have had time to arrive, we learn what sanitary experts had suspected for some time, that the besieged Ladysmith is almost as undesirable from a sanitary point of view, as the eloquent silence of military experts upon the subject would indicate it is from a military standpoint. It lies in a flat valley, commanded for cannon or even rifle fire by high hills on all sides, which at the same time shut out the breeze. The water of the Klip River which flows past the camp and town, although at present abundant in quantity is of most unsatisfactory quality, so that the troops have been obliged to depend upon a supply from wells and reservoirs, which is even now being doled out to them by the pint. A good deal of typhoid and dysentery has occurred in the town and its garrison for the past two seasons, and although fortunately owing to the rigorous precautions indicated, no outbreak has as yet occurred among the troops, it will be seen that the conditions are far from ideal for a long siege. A curious and rather unexpected cause of dysentery is alleged to be the clouds of reddish dust which fill the air continually and work their way into every house and tent and utensil, and even all packages of foods other than tins, so that considerable amounts of it have to be eaten with every meal. Its mechanical effects alone are sufficient to produce an intense gastro-intestinal irritation, and even, it is alleged, erosions of the mucous membrane leading to hemorrhage, thus reminding one of the classic administration of pounded glass or finely chopped bristles for the same purpose by Chinese poisoners. The place is also swarming with ants that cut through every wool or vegetable fabric which they can reach, even the canvas flaps of the tents. Indeed, the place seems to have been selected, as is now frankly admitted by military men, more with reference to its relation to the railway lines and the river valleys, as a convenient basis for the accumulation of supplies and reserve troops, than as an ideal camp or post calculated to stand a siege, and, as was painfully obvious in our late war in such matters, the medical department was left totally unconsulted. However, by rigorous precautions and restriction of the use of the river water the place ough' to be kept clear from any serious epidemic for the few weeks, which at most now remain before it can be relieved.

On the other hand, the arrangements for the care of the wounded in places not invested appear to have been admirably carried out. Two large hospital ships are already actively at work meeting the trains at Durban and carrying the wounded and invalids down to Capetown, from which they are transferred to the new Hospital Sanatorium situated several thousand feet above the sea-level, up and around the pines, at Wynberg, which is said to be an ideal health-resort, and, indeed, a favorite sanatoria for consumptives. The last troop-ship sent out has accommodation in its hospital ward for no less than eighty patients, and will be promptly set to work in this capacity on its arrival at Durban.

Two special hospital-trains have been provided and officered, and a third is now in construction for the Red-Cross Society at Birmingham.

Upon the surgical side the reports continue most gratifying, both as to the character and complications of the wounds made by the Mauser bullet, and the effectiveness of the modern aseptic treatment, even in the field, which was so cheeringly demonstrated in our late Cuban campaign. Less than five per cent. of the wounded in the battles of ten days to two weeks ago have died, and of course this covers far the most critical period in ninety-nine per cent. of gunshot wounds. The small amount of pain actually inflicted by these wounds is almost as remarkable as the comparative absence of shock and of subsequent hemorrhage. Case after case is reported where men have been seriously wounded with but little to attract their attention except a slight numbness in the part penetrated, and one in which a soldier was shot completely through the face, from one cheek to the other, just below the floor of the orbits, with scarcely any sensation of pain whatever, and no disability except the loss of the sense of smell and blocking up of the nostrils by blood-clots. The fatal wound of General Symons was due to a jagged fragment of a shell and not to a bullet.

The preparation of the hospital ship provided by the American women in London is still proceeding with gratifying rapidity. Nearly $100,000 have already been subscribed, and prominent firms, not merely of chemists

but also of provision dealers, are vying with one another in the generosity of their offers of stocks of free supplies. A concert is to be held this week at the Claridge Hotel at which such well-known artists as Mr. De Wolf Hopper, Miss Edna May, and last but not least, Mr. Tod Sloan, will appear to contribute to the entertainment. The date of the sailing of the "Maine" has already been fixed for Saturday, November 25th.

One of the most exciting and enthusiastic scenes which has yet occurred in connection with the departures for the front was the farewell ovation accorded to Mr. Treves by the medical students of London, chiefly, of course, from his own hospital, the London, but also from University's, St. Mary's, and, it is reported, even from the dignified Bart's. Nearly 400 of them were present at the station, and the instant the hero of the hour appeared he was lifted shoulder high and carried in triumph by the cheering crowd to the door of the carriage reserved for him. The medical student, irrepressible and irresponsible creature as he is, in some respects, can usually be trusted to have his heart in the right place, and is fully capable of appreciating the serious sacrifice which it means to a man in the prime of his activity, like Mr. Treves, to volunteer in the service of his country for a campaign of such uncertain duration as the present, to say nothing of the risks and hardships of climate and of the field.

The death from that, now fortunately rare, disease in the human subject, anthrax is reported in London this week. The infection was from the usual trade source, although from a slightly different branch of the industry from that in which the contagion is commonly caught. The patient was a curler of horse-hair for the padding of furniture and filling of mattresses and so forth, while the disease most commonly occurs at a slightly earlier stage of the hair-handling process in those who are scraping the hides or handling the wool pulled from sheep skins, hence its original name, "wool-sorter's disease." The disease presented the usual furuncular appearance, and the patient curiously enough succumbed not to it directly but to the chloroform which was being administered in preparation for an excision operation at the London Hospital.

The world "do move" even in darkest Leicester. At last night's meeting of the Guardians, one of the lady members who has been most heroic and even hysterical in her announcement of "no surrender" to the enemy, notified her intention of introducing at the next meeting a motion to rescind the resolution refusing to appoint a vaccination officer. As the resolution was reaffirmed at its last discussion by a vote of only twenty-six to twenty-three, and two of these twenty-six are now confined to their homes by serious illness, it is quite possible that the next meeting of the Board will see the capitulation of the garrison in the last anti-vaccination outpost which is in open rebellion to the law. A policy of masterly inactivity and the wearing effect of time sometimes work wonders.

Few more beautiful illustrations of the humanizing and, in the highest sense, civilizing influence and possibilities of medicine have been given than the equipment, just completed, of a special ambulance to be sent to Pretoria for the care of the Boer wounded. The cost of this has been chiefly defrayed by an English citizen and late prominent government official at the Cape, Sir James Sivewright, and it is officered entirely by British subjects, many of whom, as would naturally be expected, are inhabitants of Cape Colony and of Dutch descent. There is practically no other department of human needs in which such a beautiful recognition of the higher sympathies and interests of humanity could have been accorded, and the memory of episodes of this description will do more to heal the wounds of war, after the struggle is over, than almost anything else that could well be devised.

The London County Council has again vindicated its title to be regarded as a courageous and trustworthy champion of the sanitary rights and safety of the people under its control by reintroducing its bill for the buying out of the present water companies and securing a permanent supply in the near future from the Welsh mountains at its late meeting. It is evidently not discouraged by the effect of the calm shelving of its bill for this purpose by the Government at the last session, and proposes to fight the matter out along this line until the disgraceful paresis which seems to have fallen upon the activities of Parliament, in this respect, is galvanized into a return of vitality. Never were the advantages of a Royal Commission as a factor in the great scheme of "How not to do it" better displayed. A commission was appointed more than two years ago, has held innumerable meetings and announced its readiness to report, but rested apparently absolutely content with that. And the Government has a perfectly effective bar to any proposed reforms in the water-supply in the answer that nothing can be done until after the report of the comatose commission.

The activity of the modern Medical Officer of Health appears to have no limits. Not content with insisting upon the rigid supervision of meat, milk, fruits, and vegetables, the energetic sanitary officer of Mile End in East London, Dr. Taylor, has invaded the hitherto sacred mystery of the "store egg." Hitherto the superannuated egg has been regarded with a singular apathy, from a sanitary point of view, and its chief usefulness appears to have been as an unfailing fund of material for the humorist. But Dr. Taylor proposes to take the joke seriously and has actually pounced upon and condemned at one fell swoop no less than 4000 of these interesting remains. Of course the humorist will get his turn out of even this, and it is already wickedly suggested by some daily papers that the eggs were merely being held in stock for election purposes, especially as a very active contest is imminent in a neighboring borough. It really is somewhat singular that so little has been done toward the inspection of the state of our egg-supply, probably however chiefly for the reason that everyone is supposed to understand the risk he runs in buying suspiciously cheap eggs, and that the changes are so offensive when present that there is little risk of their being used as a direct food

supply when really unfit. If, however, anyone will take the trouble to investigate half a dozen samples of cheap pastry or cakes, with the best sanitary inspector yet invented, his own nose, he will find abundant evidence that this does not interfere with their use for cooking purposes, and the action of Dr. Taylor must be most cordially commended.

SOCIETY PROCEEDINGS.

NINTH ANNUAL MEETING OF THE NEW YORK STATE ASSOCIATION OF RAILWAY SURGEONS.

Held at the Academy of Medicine, New York City, November 16th, 1899.

THE President's address was delivered by DR. THEODORE D. MILLS of Middletown and was entitled

THE RAILWAY SURGEON AND HIS RELATIONS TO THE RAILROADS.

Every year the number of railroads who do not employ their own corps of surgeons is growing less. This is as it should be. The railroads owe it to their patrons to give them the best possible service in case of accident. Such service cannot be obtained from the chance medical men that railroad employees may be able to find in the excitement immediately following an accident. Besides there is a sense of responsibility in the railroad surgeon himself, which makes him hurry at once on a call and familiarity with series of railroad cases gives him a skill in treating them. His arrangements are all made for just such emergencies and in every way the best interests of the company and its patrons are consulted.

It is the custom to say that corporations have no souls, but certainly the railroad corporations of to-day are not open to the charge of inhumanity. Those familiar with them know that not infrequently employees who have been in their service for a long period but who have become incapacitated for work because of ailments which bear no relation to their railroad employment, however, are taken care of when they can no longer be of service. A better feeling towards railroad companies is coming up in the popular mind, and the old idea that a company should be mulcted in damages to as large an extent as possible is no longer as popular as it was. Lawyers and, unfortunately, doctors who are a disgrace to their profession still join the forces to defraud companies by damage suits in which such important affections as nervous shock or spinal concussion play a large rôle. But there is no doubt that righteous sentiment in this matter in both professions and in the public mind is lessening the evil. Railroad surgeons can do a great deal to help on the good feeling which is leading to the eradication of this evil. Their testimony in such cases should be absolutely unbiased and should favor neither the company nor the patient. Every detail at the time of the accident being carefully noted so that a proper account of the case may be given.

Railroading itself has become less dangerous in late years. A few years ago it was a rare thing to find a brakeman of much experience with his hand uninjured. The patent coupler has done away with most of this. Other mechanical improvements have been equally beneficial. While the field for the employment of the railroad surgeon is becoming more limited, there is another important subject which progress in medical science has opened up for him. We realize now much better than we did how important is prophylaxis in the matter of contagious diseases. Railroad cars are very liable to be bearers of infections. The cars that run on the lines to our mountains carry a large number of tuberculous patients. Needless to say the germs of disease may be readily spread in this way. This new field for the railroad surgeon of disinfection and sanitation of cars and waiting-rooms is an important one. It is our duty to see that it is not neglected.

DR. B. FARQUHAR CURTIS of New York then read a paper, entitled

DISLOCATION OF THE SHOULDER WITH FRACTURE OF THE NECK OF THE HUMERUS. THREE CASES TREATED BY OPERATION.

Fracture of the neck of the humerus with dislocation of the upper fragment is a rare injury and yet it has been recognized by surgeons since before the Christian era. McBurney and Dowd collected 96 cases, in 69 of which the fracture was at the surgical neck, and 27 at the anatomical neck of the humerus. In my three cases the fracture was once at the surgical neck, once at the anatomical neck and in one a comminuted fracture, the bone being split through the tuberosity. Usually the head is dislocated into the axilla, but at least two cases have been recorded where it was found under the spine of the scapula. Up to recent years, the dislocated part has usually been left unreduced. A better result was often attained in this way than after simple dislocation. In many cases, however, the result was very unsatisfactory. At times there was necrosis of the dislocated fragment; at times the pressure exerted by it on vessels caused gangrene, while the pressure on nerves caused intense pain, growing discomfort and trophic disturbances in the arm.

Some method of treatment other than that of letting things alone was needed. The old method permitted union of the bone to take place and then the reduction of the dislocation was attempted. There are in literature altogether three doubtful successes out of ten cases. Another method was to reduce at once by traction and pressure of the fingers and then set the bone so as to permit healing of the fracture. Stimson, who advises this method, recommends gentle traction so as not to tear the periosteal strands that may still connect the two parts of the fractured bone. Needless to say, traction with the heel in the axilla should not be employed in these cases. Where gentle pressure will not accomplish the purpose of reducing the dislocation no undue violence should be used. In 80 cases treated by this method, 36 successes were reported. In many of them a new joint, a pseudo-arthrosis developed. Sir James Y. Simpson recommended the beginning of passive motion as soon as possible after the accident, in order to lead to the formation of such a pseudo-arthrosis. It gives a reasonably good functional

result. The method is especially of service in cases where the bone has been broken in an attempt to reduce an old dislocation.

The third method of treating these cases is by resection and removal of the upper fragment. Curtis performed this operation in one of his cases, a young man of twenty-nine who, in a fit, fell from a wagon and was brought to Bellevue Hospital. A bony mass was found in the coracoid region. There was no deltoid flattening, some little shortening and the elbow could be brought to the side. The Roentgen-rays showed the glenoid cavity empty and seemed to show a fracture with the head of the bone displaced. The joint was cut down upon comminuted fragments of the head together with a portion of the greater tuberosity removed so as to avoid too great callous building. The result was excellent. As may be seen, the patient even when his scapula is firmly held to the chest on the side can raise his arm to the vertical position. Internal rotation is good while external rotation is lost. As teamster, he himself is of the opinion that he is able to use his arm quite as well as before.

The fourth method of treating these cases is by open arthrotomy. Until seven years ago this method was not mentioned. An American surgeon, Stevens of Ft. Wayne, was the first to perform the operation. Porter of Boston did it afterwards, and then McBurney of New York invented the hook for rotation and traction so as to get the bone into place. In one of the two cases in which Curtis did an open arthrotomy he wired the ends of the bone together and then reduced the dislocation. Four weeks after the operation there was very little movement and practically no power of rotation. Now, as may be seen here, the arm is nearly as good as ever. The result in a resection may be practically as good, but it is not as ideal an operation as the open one. Of all the operations of this kind that have been done there has been about ten per cent. of mortality. This, of course, is recognized as a high mortality, and would of itself be enough to deter surgeons from doing the operation. A consideration of the fatal cases, however, shows that in practically all of them other causes besides the operation itself were either directly responsible for the death or at least were active factors in bringing it about.

The rule in these cases is if the fracture and dislocation can not both be reduced satisfactorily to operate at once. It does not add to the danger, while the operation is easier. After the operation movement is begun without delay. Such voluntary movement as can take place beneath the shoulder-cap dressing are permitted in from ten to fourteen days after operation. After a fracture of the anatomical neck passive motion is begun three weeks after the operation; after fracture of the surgical neck five weeks may elapse.

In discussion DR. MANLEY of New York said that he had never seen fracture of the anatomical neck or the lesion described by Dr. Curtis except after efforts at reduction of a dislocation. He asked if any such efforts had been made in this case. As to the operation in general, our methods of bringing about reduction after dislocation are as yet so imperfect and may be interfered with so much by spasm of the tissues after the injury that we can not be sure when a dislocation is really irreducible. All have seen cases where the dislocation absolutely resisted all efforts one day, yet yielded readily the next. Spontaneous reduction after long unsuccessful efforts was not unknown. Ten-per-cent. mortality is high, and this has occurred in the best hands and in hospitals where the circumstances are most favorable for success. It is probable, then, that this method of treatment will not become popular with the profession, especially as the functional results even when the dislocation remains unreduced, are in many cases not at all unsatisfactory.

DR. BURNS of Long Island City said that ten-per-cent. mortality is certainly high for the operation. It would assuredly be higher in general practice. Its recommendation then seems inadvisable. With careful treatment excellent functional results can be obtained without the danger involved in the operation.

DR. CURTIS said, in concluding the discussion, that the case in which he had done resection had been one in which the comminution of the head of the bone had rendered it advisable in order to avoid excessive callous formation and consequent anchylosis. As to the loss of the function of the external rotaters he was unable to explain it. No efforts had been made in any of the cases at reduction, so that the fracture was not due to this cause. He thinks ten-per-cent. mortality serious, but even with this the operation is much less serious than is usually said in the text-books, and its prognosis is continually improving with the improvements in surgical technic. There is no doubt that with care the mortality can be reduced so that it will not exceed that for suture after fractures of the patella.

DR. ROBERT T. MORRIS of New York then read a paper entitled

WHERE HYDROGEN DIOXID IS HARMFUL.

DR. MORRIS said: There are three classes of cases in which hydrogen dioxid may easily do harm, and it is well to consider the reasons therefor, as they will help to give the indications for the use of hydrogen dioxid in general. These cases are the ones in which the drug often does good when used judiciously, but harm when used to excess. They are, first, compound fracture that has become infected; second, diphtheria, and, third, appendicitis. In all of these cases the hydrogen dioxid may do harm if used injudiciously. In compound fracture where pus burrows the hydrogen dioxid will follow it as far as it goes. But if it is used every day it produces mechanical distension of the sinuses, it destroys the pus, but it also destroys the new plastic lymphatic tissue which is being made ready for the formation of connective tissue, and thus keeps the fistula open for a long time. If after awhile some stimulant preparation, such as a weak solution of the silver salts or balsam of Peru, were used they would bring about closure of the sinuses. It saves life at first by averting septic crises, but what is a virtue at one stage becomes vicious later, and it delays convalescence.

In diphtheria it undoubtedly removes the patch of co-

agulated necrotic tissue in the midst of which microbes are growing and producing the toxins that cause the constitutional symptoms of the disease, but it also injures the cells of the mucous membrane. After the application of hydrogen dioxid for several days the superficial epithelium becomes less resistent, the infection spreads, and the false membrane is found all over the throat.

In appendicitis the use of hydrogen dioxid at the beginning when the abscess is first opened, enables the surgeon to get rid very effectally of toxin-bearing fluids. But, as in the compound fracture, it hinders repair by destroying the new plastic lymph and keeps the fistula open for a long time. Very often in these cases of persistent fistula where hydrogen dioxid has been used right along the only treatment that is needed to bring about closure of the fistula is to put on a pad and leave the patient alone.

DR. BELL said that the use of hydrogen dioxid in diphtheria carried with it certain dangers, which it was well to bear in mind. In one case recently he had seen a fatal result after the use of peroxid, though tracheotomy was done immediately when symptoms of suffocation ensued. At the autopsy it was found that almost a complete cast of the larynx had been loosened by the hydrogen dioxid and then aspirated beyond the bifurcation of the trachea, where it caused suffocation. In another case a large patch of false membrane was loosened in the same manner, and while it did not cause a fatal issue it was aspirated into the trachea and only gotten rid of after a severe attack of suffocation and coughing.

DR. STILLING of Concord said that a warm solution of formalin one-half per cent. has in his hands proved the best antiseptic for use in the cases in which hydrogen dioxid was formerly much recommended, but it is now being generally abandoned. It has practically none of the disadvantages of the peroxid, does not destroy the granulation tissue, nor keep sinuses open, and yet has all the antiseptic effect of the former drug.

In concluding the discussion, DR. MORRIS said that his experience had taught him to use hydrogen dioxid for the first dressing of a wound and afterwards as a routine practice to employ other antiseptics. If there was no septic reaction the other antiseptics were continued. If there were fever, rapid pulse, and some constitutional symptoms indicating absorption of septic material, then hydrogen peroxid was used a second or even a third time. With reference to fistulæ, some of them remain open for a month despite any treatment that may be used. Some for several months. In one recent case the fistula remained open for two years, the whole cecum sloughing out. When fistulæ will close and when they should be treated by letting alone rather than by active intervention only wide experience will help the surgeon to determine.

As to formaldehyd, while it is undoubtedly an excellent antiseptic, there are certain features in its use which do not promise as well as the employment of hydrogen dioxid. Thick masses of infected lymphatic tissue, for instance, will not be penetrated by the formaldehyd. Necrotic tissue also resists its antiseptic effect. Blood coagula are not dissolved and infective agents may germinate in the midst of them. The hydrogen dioxid forces its way because of the boiling action incident to the setting free of gases when in contact with albuminous substances and so penetrates every part where there is pus. The mere mechanical washing out with formaldehyd will never accomplish this.

The next paper was read by DR. H. JOHN L. EDDY, and was entitled

EMERGENT SURGERY.

DR. EDDY dwelt on the necessity for being able to make use of whatever means might be at hand in emergencies in order to make surgical measures as nearly aseptic as possible. The engine will supply hot water for this purpose, and one must learn to pick out the most intelligent among the bystanders as an assistant. Care is very important at the first dressing, because on it to a great extent will depend the aftercourse of the case. If the first dressing be carefully applied, there would be no need to open amputation wounds or other aseptic operation sites before eight or nine days have passed. It is important in these operations done at the place of the accident to pull down the nerves and cut them off some distance above the line of amputation in order to avoid their subsequent entanglement in the scar.

DR. BURNS of Long Island City said in discussion: Much can be done now in the way of carrying aseptic dressings and aseptic instruments with one. Towels and gauze and suture material thoroughly sterilized and wrapped in wax paper can be easily obtained and carried without occupying much space. Compressed sponges are an important addition to the railway surgeon's armamentarium. Pledgets of cotton are liable to be infected, or cannot easily be rendered aseptic. These compressed sponges take their place very well. Sterilizers are made so small now that they can be carried with one, and an alcohol lamp completes the outfit. Thus the sterilization of instruments may be accomplished absolutely independent of circumstances.

DR. MORRIS said that for emergency cases he found asbestos wool an excellent dressing. It can be easily rendered absolutely aseptic by burning it. Where operations are done at a distance from all surgical conveniences this asbestos wool may be taken out every day and heated on a shovel so as to become absolutely aseptic and then replaced.

DR. MANLEY of New York then presented

SOME INTERESTING CASES INVOLVING BONE LESIONS.

The first was a case involving a fracture of the upper fourth of the ulna with a dislocation of the head of the radius. The muscles of the hand wasted after the accident, motion was very much restricted, and there was absolutely no supination. The hand was cold, perspiration was profuse, vitality of the skin was greatly lowered. The location of the lesions pointed to an involvement of the median nerve. Several surgeons have discouraged operative interference. An incision showed that the bones were welded together by solidified callous in the upper part. This was split up, the head of the radius was found to be pressing on the median

nerve and was sawed off. The functional result is, as may be seen, excellent.

In a second patient, a freight conductor, a car passed over the upper part of his arm. There was a fracture in the upper third of the radius and ulna, a fracture of the lower fourth of the humerus, a fracture in the upper third of the humerus. My rule is never to amputate, by primary operation, no matter how unpromising the case looks. This man's arm has been saved to him by this rule, and will undoubtedly be of a good deal more use than any prothetic apparatus would be.

In another patient, also a freight conductor, the accident happened exactly as did the previous one, by tripping over one of the switch conduit boxes in the yards. It was his foot instead of the arm that was run over. A typical amputation by one of the classical methods was not attempted, but all the tissue possible was saved. The result, you see, is a good, serviceable stump. These cases all plead for more conservative work in emergency surgery.

REPORT OF MEETING OF THE LABORATORY COMMITTEE OF THE AMERICAN PUBLIC HEALTH ASSOCIATION.

Held in the Laboratory of the Medical Sciences of the University of Minnesota, Minneapolis, Minn., October 30, 1899.

PROFESSOR W. H. WELCH of Johns Hopkins University, the Honorary Chairman, opened the meeting with an address in which he called attention to the benefit to be derived from the meeting of the laboratory workers at the Association. He then spoke of certain lines of work that he deemed worthy of the committee's consideration.

He suggested the value of further investigations with reference to the danger that really results from infection from tubercular cattle, and to ascertain amid varying exaggerated and underestimated reports the exact degree of danger. Concerning typhoid fever, he deplored the experiences during the recent war, the mistakes in diagnoses, and the absence of application of hygienic principles, pointing out the necessity of better methods of diagnosis of typhoid and malarial diseases, and of the teaching of hygiene in the medical schools. He mentioned the fact that the problem of disinfection is a subject of constant interest, and that it remains to be proved whether in certain diseases it is necessary to disinfect at all.

He touched upon the question of sewage disposal by natural methods, and then indicated the broad biological subject of the differentiation of bacteriological species.

STUDIES UPON THE DISTRIBUTION OF CERTAIN VARIETIES OF DIPHTHERIA BACILLUS.

These papers were presented by DRS. WESTBROOK, WILSON, and MCDANIEL of Minneapolis. Out of 263 children in health that were examined, twenty-five per cent. showed no diphtheria-like organisms in either nose or throat, while seventy-five per cent. showed the nose and throat infected. In classifying diphtheria bacilli they fall into three groups depending upon microscopical appearances. Group 1, includes typical diphtheria bacilli; group 2, even staining and irregular bacilli; group 3, short, even bacilli. The bacteria of group 2 were more frequently found than those of group 1. Infection of the nose was found to occur more frequently than infection of the throat, in the proportion of ninety-four per cent. and sixty-one per cent. respectively. The bacteria of group 1 were more frequently found in the throats, and those of group 2 in the noses. Another examination of 50 to 100 synchronous throat and nose cultures gave somewhat surprising results in the large percentage of typical granular and irregular diphtheria bacilli found, while even staining varieties were more numerous.

The methods of recording the morphological characteristics of diphtheria-like micro-organisms studied were as follows: The making of synchronous nose and throat cultures of healthy children living under similar conditions in several State institutions, and of healthy children in a town where diphtheria was never absent, and of the public-school children in three towns of the State.

In all of these cases there was a percentage of typical granular bacillus diphtheria, particularly in the nose. Types resembling the atypical form were met with much more frequently. In comparing the results of examinations from various sources the following points were noted: Each individual type was found to persist in a given pure culture throughout several generations, and to be present in all stages; the tendency of each type to develop a few individuals of one or several of the other types was marked; changes from non-granular forms of the same size and conversely were, perhaps, not more frequent than changes in form and size with preservation of the original characteristic staining reactions.

A STREPTOTHRIX FORM ISOLATED FROM WATER RESEMBLING DIPHTHERIA BACILLUS

was presented by DR. J. J. MCKENZIE of the Board of Health of Toronto. In the course of the examination of a sample of water there appeared in the plates small colonies with fringed margins, which proved to be a streptothrix. Its growth, which was followed on all the ordinary media, was at first slow, but after several transfers it became more luxuriant, especially at 37° C. On glycerin-agar and blood-serum the growth had many of the streptothrix characters. In bouillon and on potato it did not grow well. It did not ferment lactose or glucose. Its growth on potato was not luxuriant, and it showed a tendency on the latter to break into shorter segments until it was almost coccus-like. It proved to be but slightly pathogenic for guinea-pigs.

BRANCHING DIPHTHERIA BACILLI

were described by DR. HIBBERT HILL of Boston. The indefinite "ray fungus" of actinomycosis, after various vicissitudes, became classified as a definitely branched form, a streptothrix. The similarity in many respects of the bacillus tuberculosis to the ray fungus has obtained

for the latter recognition as a branched organism, it being in all probability also a streptothrix. Already a common percentage for both organisms is suspected. The organism for leprosy and the organism of glanders also sometimes show branching. The occasional branching of the diphtheria bacillus has been recognized for years. Described at first as a peculiarity, explained as a result of degeneration, it is now beginning to be recognized as a definite characteristic. The organism of diphtheria seems likely before long to be removed from the class bacillus, and placed in the class streptothrix, as a degenerate form of this genus. The fact that branching occurs at times, in fifteen-hour cultures, as well as in much older cultures, is already established. It may occur on nutrient agar as well as on Loeffler serum. An important point is to determine the frequency of its occurrence.

The papers treating of diphtheria organism were spiritedly discussed both from the standpoint of the practising physician and the bacteriologist by DRS. WELCH, WESSBROOK, HILL, RAVOLD, and FIELD.

THE SIGNIFICANCE OF CERTAIN GAS-PRODUCING BACTERIA OF NON-COLON TYPE IN SANITARY ANALYSIS

was the subject of papers prepared by H. L. RUSSELL, and V. N. BASSETT, of Madison. Among other things they said that to insure the elimination of other species that can be cultivated at blood heat, it is better to isolate in pure culture the gas-forming species. The method employed is to make a litmus-lactose agar culture of a sample of water, and if acid colonies develop, transfer these to glucose fermentation-tubes. The separation does not usually require more than thirty-six hours and from the separated colony on the litmus agar glucose free broth is inoculated for the indol test, cultures in glucose and lactose, bouillon, litmus-milk and gelatin slabs are made. These five subcultures will permit of a differentiation in about two to three days more.

Of leading importance in this differentiation is the character of the fermentation in different sugars. Where gas is produced, it is a mixture of CO, and an explosible residue that is generally H. The relation of these gases to each other in many species of aerogenic bacteria is fairly constant. Theobald Smith has designated this relation of H/CO as the gas-formula. The characteristic relation for the colon type of organism has been shown by him as well as others to be H/CO-2/1. The classification on the basis of their gas formula of many of the aerogenic forms found in water supplies shows at once two well differentiated groups. Those having a formula of 2/1 as presented by the colon bacillus, and those having an inverted formula of 1/2. These two classes are often represented, the first one in those waters that are polluted with fecal discharges; the second in open waters in which the possibility of sewage pollution is not absolutely prevented, but in which the more probable origin of the gas-forming organism is from upper soil layers or decomposing vegetable or animal matter. Transitional types are also more or less frequent. Sometimes the gas-formula exceeds 2/1; then, again, the amount of hydrogen equals the CO, making the formula 1/1.

A continued study of gas-forming bacteria from water leads us to believe that some types of these groups are subject to considerable variation when cultivated on artificial media for a length of time. In our experience this tendency to variation has expressed itself mainly in the fermentations function, more especially as to the amount of gas produced, although considerable change in gas formula has also been noted. This has been more apparent in the 1/2 and the transitional or 1/1 type than it has in the distinctly colon class. The 1/2 group seems to be the most variable in its gas relationship, the 1/1 group varying in time, but more slowly.

While an inspection of the gas formula of those types in which the H is equal to or less than CO at once serves to differentiate them from the colon type, those species possessing the formula 2/1 or thereabouts cannot safely be classed as colon on this basis alone. In this case the other cultures aid in determining colon affinities. The determination of the gas formula is of prime importance in determining the relation of any aeroganic organism. While it cannot settle the question positively whether an organism is colon-like or not, the presence of an aberrant colon formula as 1/1, or more especially 1/2, signifies the non-colon relation of the bacterium.

NOTES ON BACTERIAL WATER ANALYSIS

by E. O. JORDAN and E. E. IRONS of Chicago included a discussion of the question of transportation. It seems to be assumed by some that a sample packed in ice will arrive at its destination in substantially the same condition as when it was drawn from the source. There are however conditions in which these assumptions prove strikingly unwarranted.

In one instance three samples of polluted river water of a temperature of about 28° C., were plated immediately after collection and gave respectively 535,000, 412,000, and 329,000 colonies. The bottles were at once packed in ice and shipped to Chicago. They did not arrive until forty-eight hours had elapsed; the temperature of the water case was 21° C., and the numbers obtained by plating—namely, 54,500, 50,500, and 73,500—were much lower than the initial numbers. There is no escape from the conclusion, therefore, that in some cases packing in ice is followed by a rapid and marked decline in the number of colonies. It sometimes occurs that instead of a decline in numbers in water samples packed in ice, a considerable increase may be observed.

The initial temperature determines to a large extent the course of events. In the warmer seasons of the year, the vitiation of numerical results by transportation probably reaches its maximum, whether the water sample be shipped without any attempt to modify its temperature, or whether it be packed in ice. The influence of ice-packing upon such colon bacilli as may be present in polluted water does not appear to be injurious.

In regard to dilution it is found that results obtained by plating 1/10 c.c., for example, will be found to

agree less closely with one another than those obtained from 2/1-10 dilution with sterile water; but if there are more than about 100 colonies to the plate, there may be difficulty arising from the suppression or obscuration of colonies.

Not only is the exact reaction of media important, but variations in the compositions of the peptones used have been shown to be of great significance. Quite recently a paper by HESSE and NIEDNER (*Zeitschr. f. Hyg.*, xxix, p. 454) has appeared in which a substance composed largely of albumose and known by the trade name of Nahrstoff Heyden, is recommended as a bacterial nutrient. We have recently procured some Nahrstoff Heyden, and have obtained with it numerical results much higher than those secured with the ordinary nutrient media.

SOME POINTS ON THE DIFFERENTIATION AND CLASSIFICATION OF WATER BACTERIA

were present by GEORGE W. FULLER and GEORGE A. JOHNSON of New York.

This subject involved the consideration of the following points: Vitality of the organism at time of cultivation for classification data; composition and preparation of culture media; temperature of cultivation; period of cultivation. With the view to eliminate in a measure, if possible, the effect of debilitation of the bacterial cells, which may exist prior to their isolation from water, the pure culture is subjected to a preliminary cultivation. It is then transplanted to nutrient broth; from the latter, after three days' development at 20° C. to gelatin plates; thence, after the same period and temperature of cultivation, back to an agar-tube; and finally after the agar-tube has developed for three days at 20° C. the conventional media are seeded.

A chart of bacteria in the Ohio River water at Cincinnati represented tests which gave clearly defined results capable of expression by the plus or minus sign. The second feature of the chart was the arrangement of species of bacteria into thirteen groups: (1) Fluorescent forms; (2) red chromogenic forms; (3) orange chromogenic forms; (4) yellow chromogenic forms, (5) violet chromogenic forms; (6) non-fluorescent, non-chromogenic, gelatin liquefying bacteria, forming proteus-like colonies on gelatin; (7) non-fluorescent, non-chromogenic, gelatin liquefying bacteria, forming subtilis-like colonies on gelatin; (8) non-fluorescent, non-chromogenic, non-proteus, and non-subtilis-like bacteria, which liquefy gelatin and ferment carbohydrate with the production of gas; (9) bacteria conforming to 8, except that fermentation of carbohydrate takes place without the formation of gas; (10) bacteria conforming to 8, except that no fermentation of carbohydrate occurs; (11) non-fluorescent, non-chromogenic, non-gelatin-liquefying bacteria, which ferment carbohydrates with the production of gas; (12) bacteria conforming to the specified characteristics of Group 11, except that fermentation of carbohydrate takes place without the production of gas; (13) all bacteria comforming to 11, except that no fermentation of carbohydrate occurs. The colors embraced in the four chromogenic groups may be described as red, color produced by bacillus prodigiosus on agar; yellow, color produced by the growth of sarcina lutea on agar, with the dividing line between this and the orange group at the yellow-ochre has produced bacillus ocraseus on agar; orange, this color begins just below the yellow-ochre stage. The true orange is the same as that produced by bacillus aurantiacus on agar; violet, the same as that color produced by the growth of bacillus violaceus on agar.

THE QUESTION OF STANDARD METHODS FOR THE DETERMINATION OF THE NUMBERS OF BACTERIA IN WATERS

was discussed, and attention called to the advisability of universally adopting a system in connection with the composition of culture media; reaction of the media; dilution of sample of water, if such be made, and the period and temperature of development.

With a view to obtaining as complete development of water bacteria, and in a shorter time than is now the case, the most promising results have been obtained by the use of a simple medium, consisting of ordinary meat infusion, with twelve per cent. by weight of gelatin, but with the precaution that the medium shall not be overheated.

In repeated instances at Louisville and Cincinnati this medium yielded results in two-days' development at 20° C., which are at least fifty per cent. higher than those obtained from the regular nutrient gelatin after a period of three-days' development at the same temperature.

THE OBSERVATION OF ODOR AS AN ESSENTIAL PART OF WATER ANALYSIS,

was spoken of by DR. GEORGE C. WHIPPLE of Brooklyn, N. Y.

The "cold odor" is observed by shaking the sample in a partly-filled 2-liter bottle. The "hot odor" is observed by heating 200 c.c. of the sample in a beaker covered with a watch-glass to a point just short of boiling, and making the observation as soon as the water has cooled sufficiently.

The following scale of terms for estimating the intensity will be found convenient: 0. None. No odor. 1, Very faint. An odor that would be scarcely perceptible to the consumer, but one that could be detected in the laboratory. 2, Faint. An odor that might be detected by the consumer. 3, Distinct. An odor sure to be detected by the consumer, and one that would make the water looked upon with disfavor. 4, Decided. An odor that would force itself upon the attention, making the water almost unpalatable. 5, Very strong. A term reserved for extreme cases where the odor is very intense. By using this numerical scale in connection with abbreviations of the adjectives denoting the quality of the odors the descriptions may be completely recorded, and made to form a part of the analysis. Thus, 2vg would mean that the water had a vegetable odor that might be detected by the consumer; 3f, that the water had a fishy odor sure to cause remark by the consumer, etc. The following are some of the common adjectives likely to be

used. Each may be abbreviated by a single letter: V, vegetable; e, earthy; p, peaty; a, aromatic; g, grassy; f, fishy; m, moldy; u, unpleasant; d, disagreeable.

After a thorough discussion of this subject DR. SWARTS of Providence moved that a committee be appointed to present at the next meeting a standard formula for the analysis of water which should be the recommended method of analysis of this Association.

DR. WELCH, the Chairman, announced the following names for that committee: Mr. George W. Fuller, Professor H. L. Russell, Professor E. O. Jordan, Dr. Adolph Gehrmann, Dr. Wyatt Johnston, Mr. G. C. Whipple, and Mr. H. W. Clark.

THE IDOMETRIC DETERMINATION OF SMALL QUANTITIES OF CARBON MONOXID,

by DRS. LEONARD P. KINNICUTT and GEORGE R. SANFORD.

The method of determining carbon monoxid by oxidation to carbon dioxid has not, until the past ten years, received much attention. This oxidation can be accomplished by the use of many oxidizing agents, but of all those that have been proposed iodin penta-oxid is, from our experience, the one that can best be used for the determination of small amounts of carbon monoxid.

The apparatus used was, with slight changes, that described by Nicloux. Twenty-five grams of iodin penta oxid was placed in a small U tube, which was suspended in an oil bath and connected with a Wolff blood-absorption tube containing ½ gram of iodid of potassium dissolved in 5 cubic centimeters of water. The tube containing the iodin penta-oxid was also connected with two U-tubes, one containing sulphuric acid, the other small pieces of potassium hydrate, so as to remove from the air to be analyzed (before it came in contact with the iodin penta-oxid) all unsaturated hydrocarbons, sulphid of hydrogen, sulphur dioxid, and similar reducing gases. In all the experiments the oil bath, in which the U tube containing the iodin penta-oxid was suspended, was heated to 150° C., as preliminary tests showed that the reaction was not a quantitative one at lower temperatures.

DISCUSSION.

PROFESSOR ROBINSON, Brunswick: It is well known that those inspectors engaged in public health work have been unable thus far to detect the presence of this gas in the air of rooms, and if they are able to detect it by the method of Dr. Kinnicutt a great step has been taken in advance.

DR. WELCH: There is great danger from gas leakage from a stove and from gas. It is no doubt injurious to the health of occupants of rooms, and cannot be readily detected.

PROFESSOR RICHARDS, Boston: In 1883 and 1884 a great deal of work was done in our laboratory with this method, using a modification of it. I have used that at various times since in cases of contamination of air of recitation rooms.

THERAPEUTIC HINTS.

For Dysmenorrhea.—

℞	Nitroglycerin	gr. $\frac{1}{2\frac{1}{5}}$
	Spiritus	*m.* xx
	Aq. dest. . . . q. s. ad.	℥ iiss.

M. Sig. Two teaspoonfuls every fifteen minutes until physiological effects of drug appear.—*M. G. Price.*

For Severe Epistaxis.—

℞	Gelatin	part i
	Normal salt sol.	part xvi.

M. Sig. External use. Absorbent cotton is saturated with this solution, and used as a nasal plug. An aseptic coagulum forms which checks further bleeding.—*Da Costa.*

For Acute Bronchitis.—

℞	Ammonii carb.	gr. xxx
	Tinct. hyoscyami	℥ iv
	Codeinæ	gr. ii
	Syr. prun. virg.	℥ iv
	Aq. camphoræ . . q. s. ad.	℥ iv.

M. Sig. One teaspoonful every two hours.—*Hersvirsch.*

For Pediculosis Capitis.—The simplest and most effective way of getting rid of both parasites and nits is to shave the head and scrub it with soap and water. When for reasons of age or sex it is desirable to preserve the hair, it can be powdered with powdered pyrethrum, staphisagria, or sulphur, which will kill the lice. Nits and adults are both reached by hot vinegar or camphorated alcohol, or the following solution, which is highly recommended:

℞	Bichlorid of mercury . . .	1 part
	Vinegar	300 parts.

Another prescription is that of DESCROIZELLE:

℞	Tinct. pyrethri	℥ i
	Tinct. rosmarini } aa.	
	Tinct. cinchonæ } . . .	℥ ss
	Spiritus	℥ i.

M. Sig. External use.

An alcoholic solution of naphtha is also said to be very effective. Kerosene and the tincture of delphinium are old stand-bys, but the former is objectionable on account of its odor and greasiness, and the latter on account of its expensiveness.

Ointment for Rheumatism.—

℞	Ac. salicyl. pulv.	℥ i
	Ol. terebinth.	℥ i
	Lanolini	℥ i.

M. Ft. unguentum. Sig. Rub into the skin for five minutes after cleansing it with soap and water.—*Husson-*

For Prostatitis.—

℞	Ichthyol	℥ i
	Ol. theobrom.	℥ vi.

M. Ft. suppos. No. xii. Sig. Use one suppository at night and one in the morning after defecation. Under this treatment the pain, sense of pressure, etc., are said to decrease rapidly, and the hypertrophy to become sensibly diminished.—*A. Freudenberg.*

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXV. NEW YORK, SATURDAY, DECEMBER 16, 1899. NO. 25.

ORIGINAL ARTICLES.

THE TREATMENT OF PNEUMONIA AS BASED UPON RECENT VIEWS AS TO ITS PATHOLOGY.*

BY ANDREW H. SMITH, M.D.,
OF NEW YORK.

IN using the word pneumonia I wish to restrict it absolutely to the form variously designated as lobar, fibrinous, or croupous pneumonia; the form that in typical cases is ushered in abruptly by a chill accompanied with fever, which fever after a course of from four to nine days, if the patient is to recover, ends suddenly by crisis.

For the sake of brevity I will quote, from a paper recently contributed by me to the "Twentieth Century Practice," my views as to the sequence of events taking place in an attack of pneumonia:

"1. The occurrence of some cause of depression, either local or general, which favors the germination of pneumococci, already present in some one of the smaller tubes.

"2. The formation of a colony that spreads until it reaches the group of air vessels that are terminal to the tube in question.

"3. The setting up of an irritation in these vesicles, causing a fibrinous exudation, an emigration of leucocytes, and a diapedesis of red cells from the functional capillaries.†

"4. The formation of a colony of pneumococci in the medium afforded by this exudate.

"5. Arrest of the blood stream in the functional capillaries, followed by accumulation of free pneumic acid in the parenchyma of the affected area.‡

"6. Overflow of exudate into neighboring lobules, starting the process in them also.

"7. Arrest of germ growth by exhaustion of the medium and the accumulation of free acid in the tissue of the lung. Up to this time there has been a constant formation and absorption of toxin.

"8. Retrogressive changes in the exudate preparatory to its removal by absorption.

"9. Probably, in this latter process, formation of an antitoxic principle.

"10. Entire removal of the exudate and restoration of the vesicle to its normal condition.

"11. Resumption of the functional capillary circulation."

First, a few words as to what pneumonia is not, and then a few as to what it is. Pneumonia is not an inflammation of the lung. You can create a pneumonitis at will in any of a dozen or a hundred ways. There is only one way in which you can produce a pneumonia. You may bruise, tear, pierce, or scald the lung, you may force acrid gases into it; nay, you may introduce any foreign substance into it, including, with one exception, any conceivable pathogenic organism, and you will not get pneumonia as the result. You may get inflammation, suppuration, even gangrene, but it will not be pneumonia, and it will not have the clinical history of pneumonia. But there is just one thing that if introduced into the parenchyma of the lung will produce pneumonia always and without fail, and that is the pneumococcus. If you inject a little active pneumonic sputum through the chest wall into the substance of the lung, you will inevitably cause genuine pneumonia with all that clinically belongs to it. These facts are sufficient to differentiate between pulmonary inflammation and pneumonia, but there are other facts in the history of the latter and especially in the occurrence of crisis, which are equally significant but which I need not stop now to consider.

Nor is it enough to admit the infectious nature of the disease and to define pneumonia as an inflammation excited by the presence of a specific parasite. The parasite is there unquestionably, but it does not excite inflammation. Inflammation is a perverted nutrition, but in pneumonia the nutrition of the pulmonary parenchyma does not suffer. At the most there is only a certain amount of desquamation of the epithelium, the walls of the air-cells remaining intact and ready to resume their function the moment the exudate is removed from within the cell and stasis in the functional capillaries is relieved. There is nothing left that represents the effects of inflammation, no interstitial deposit, no

* Read before the New York Academy of Medicine, November 2, 1899. For discussion, see p. 814.

†The walls of the pulmonary capillaries being adapted for the transmission of gases possess an extreme tenuity not equalled elsewhere in the body. Moreover, they are separated from the alveolar cavity only by a single layer of pavement epithelium which affords them almost no protection or support. Hence they are exposed to the full current of the irritation caused by the micro-organism which invades the air-cell and of the toxin it produces. Under this irritation the capillary wall undergoes a partial degeneration which favors the escape through it of the various elements that go to make up the pneumonic exudate.

‡As to this accumulation, see p. 44 of vol. xvi, "Twentieth Century Practice of Medicine." Throughout this paper the above-mentioned article has been freely used.

obliteration of vessels, no loss of substance, no new formations. The tremendously active process that has been going on in the lung, enough in any other organ to have spoiled the structure for future use, has vanished and left no trace behind. And for this what have we to thank? Simply the independent nutrient circulation heretofore entirely overlooked in its relation to the pathology of pneumonia. While the functional capillaries under the specific irritation caused by the parasite have been permitting, as we have seen, the exudation of fibrin, the emigration of leucocytes, and the diapedesis of red corpuscles into the air-cells, until at last the pressure of the alveolar contents has become more than the thin walls of the right heart could overcome, and complete stasis of the functional circulation has taken place, the sturdy left heart has been taking care of the nutrition of the suffering area, and pumping its blood regularly and steadily through the nutrient capillaries. Had it failed for a moment to do this the battle would have been lost, and wholesale necrosis would have been the inevitable result.

Here then we see at the same time, and in the same area, the action of the right heart completely suspended and the action of the left heart intact. From the nature of the case this could take place nowhere else than in the lung, *and this removes pneumonia out of the category of diseases for which analogous conditions can be found in other parts of the body.* For this reason all our notions of inflammation in general are *wholly inapplicable* to the condition in question.

But how, it may be asked, do we know that there is this restriction of the process to the functional circulation? How do we know that both circulations are not involved? The answer to this is found in anatomical conditions easily demonstrated. In the pneumonic lung we find the capillaries which are continuations of the branches of the pulmonary artery completely thrombosed, and this thrombosis extends back toward the heart until the pulmonary branch is reached that goes to the affected lobe. If the entire lung is involved the thrombus will extend back to the bifurcation of the pulmonary artery. Not infrequently the clot grows out into the lumen of the latter vessel, and sometimes this projecting portion breaks off and is carried by the blood current into the unaffected lung, producing immediate death.[1]

Contrast with this the condition of the nutrient capillaries derived from the bronchial arteries. These are found completely free, so that the blood might circulate through them unhindered and supply the parenchyma of the lung without interruption. It is true that in a small number of cases a branch of one of the bronchial vessels becomes obstructed, and then we get a corresponding area of gangrene, just what would befall the whole affected portion of the lung if instead of a pneumonia we had a pneumonitis of the same colossal proportions.

If, then, in pneumonia we are not dealing with an inflammation, how are we to characterize the local process? The answer to this is that we have a process of germ culture going on in a culture medium, which medium is supplied from vessels that do not participate in the nutrition of the part, but at the same time are susceptible to the action of the specific irritant furnished by the specific germ in question. Each air cell thus becomes in effect a tiny test-tube in which a colony is growing, the exudate serving as a culture medium.* It is this culture that constitutes the essence of pneumonia. The complicated manifestations that complete the clinical picture are epiphenomena. Why this peculiar local reaction should follow this one form of irritation and no other we cannot tell, any more than we can tell why the skin should react to the poisonous emanation from the rhus toxicodendron in a manner different from its reaction to all other forms of irritation. But medicine is full of similar pathological, as well as biological, puzzles.

Two of the epiphenomena attending the culture process in the lung are of extreme importance, constituting singly or together the chief menace to life. These are, first, the infection of the system by the toxin formed in the lung, and, second, the embarrassment of the respiratory function resulting from the presence of the exudate in the air-cells. From the first of these we have the chill, the fever, the nervous and muscular prostration, and a host of complications depending on toxemia, some one or more of which arise sooner or later in a large number of cases. From the second we have the tenddency to asphyxia, and from the two combined the ever-present danger of failure of the right heart.

This being a very brief review of the pathology of pneumonia as it appears to me, let us see in how far it affords a basis for a rational treatment. Heretofore the treatment of pneumonia has been almost wholly symptomatic, and on the whole we must admit that it has been far from satisfactory. In hospital practice the world over from one-fourth to one-third of the cases have proved fatal. In private practice the results have been somewhat more favor-

* A schematic illustration will sometimes serve a useful purpose. If a hemorrhage should take place from a villi within the urinary bladder and the clot should become infected by germs from without, we should scarcely call this a cystitis, although the vesical mucosa might suffer somewhat from the process going on in the viscus. The case would not be materially altered if the germs were introduced as the first step, and by their irritation induced the hemorrhage, provided the process ceased with the removal of the clot.

able. But the fact still remains that pneumonia destroys more lives than any two other acute diseases combined.

Within the present decade, however, there seems to have been a dawning of a better era. With the recognition of the specific microbe came necessarily the idea of an anti-microbic treatment. Unhappily, development along this line has been hindered by the persistent hold upon the professional mind that the idea of a pneumonitis has maintained. The utmost concession has been that the specific organism excited a local inflammation, which once excited was like any other inflammation. The matter has been still further complicated by the assumption in some quarters that the infection was first general, and afterward became localized in the lung. According to this view, the pulmonary lesion was the specific eruption that accompanied pneumonic fever, as the cutaneous eruptions accompany the fevers of measles, scarlatina, and smallpox. The one idea that has found most difficult acceptance is that the beginning of pneumonia is the lodgment of the pneumococcus in the air-cell, and that all the other phenomena are subsequent to and consequent upon this lodgment, no matter in what order they become apparent, either to the patient or to the physician. Thus, the patient has pneumonia before he has fever, or a chill, or a stitch in the side, or begins to cough. He will probably have had pneumonia for many hours, or perhaps some days before the local changes attain to such a development as to make themselves apparent by the clumsy and insensitive methods of auscultation and percussion. Yet with what dogmatic assurance we assert that there is no pneumonia present if we fail to detect percussion dulness or a crepitant râle. If we are especially cautious we will say that the patient may get pneumonia later, but he certainly has not got it now. Because the flames are not bursting from every window we ignore the smouldering fire that is eating its way through the interior of the building.

Grasping fully that all the phenomena of the disease center in the colonies of bacteria growing in the air-cells, we have at least the basis for rational therapeutic effort. The problem before us is, first of all, to arrest or inhibit this growth. We shall be assisted in solving this problem by a knowledge of the peculiarities of the organism with which we have to deal. Fortunately, the pneumococcus lanceolatus has been studied by many competent observers, and its life-history and conditions of growth are thoroughly established. The facts most important for our purpose are, first, that "the life of the organism is short, not exceeding ten or twelve days at the most in artificial cultures. The second is, that of all known germs this is perhaps the most sensitive to its environment, laboratory experience showing that it can be cultivated successfully only by the most careful attention to its habits and peculiarities. The slightest deviation from the conditions these impose puts an end to its growth. Furthermore, the probability of successfully inhibiting the action of a germ through the influence of an agent diffused in the blood is greatly enhanced if the germ is located in the lung. This is due to the fact that the whole mass of the blood passes through the comparatively small pulmonary circulation every time that it traverses the vastly greater systemic circuit. Hence any substance in the blood comes into much more intimate contact with a germ in the lung than it would with a germ placed elsewhere, and the assault is proportionately concentrated and energetic."

"It is true that to be fully effective a germicide designed to act within the air-cell must be employed before the circulation in the functional capillaries is arrested. After such arrest it can reach its destination only by the very narrow channel of the nutrient blood-supply. But as the pressure of the exudate is the ultimate factor in closing the functional vessels (whatever coagulating influence the morbid process may have exerted) it is not until consolidation is complete that access through these vessels is entirely cut off."

Inasmuch as the pneumococci are growing in a medium which is derived directly from the blood, it is clear that their pabulum will partake of any substance with which the blood may be charged at the time when the exudate is separated from it. Hence, if we could anticipate the lodgment of the cocci in the air-cell by impregnating the blood sufficiently with a substance inimical to the growth of the organism, we should stand a chance of forestalling the local process and thus entirely preventing the disease. Such early action, however, is seldom practicable, and when the air-cell is once filled with exudate but little can be done thereafter to influence the culture process going on within it. This process will continue until the quantity of medium in the cell is exhausted or until the accumulation of pneumic acid in the lung tissue arrests the growth of the germ. But the local process is always at first a spreading one, and there is no reason why the invasion of new cells may not be prevented, thus limiting the disease to the area already attacked.

This being the theory of the antimicrobic treatment, let us see what progress has been made toward realizing it in practice. For years past and long before anything was known of micro-organisms certain remedies have had more or less reputation as tending to cut short pneumonia. Calomel was one

of these, and many of us remember with what confidence the late Dr. Leaming prescribed his "sedative dose" of 40 or 50 grains, and how often this dose was followed by a prompt fall of temperature going on in many cases to complete defervesence. In this he was building on the foundation of the older clinicians, who placed great faith in the value of mercury as an "antiphlogistic" in pneumonia.

Fifty years ago very few would have had the hardihood to treat a case without it. We can see now that it was not its "antiplastic," but its antigermic effect, if I may coin a word, that gave it its value. The pneumococcus is exceedingly sensitive to the mercuric salts, and enough of the calomel would be converted into bichlorid to give a decided character to the blood and to the exudate separated from the blood. Indeed, the evidence at hand would indicate that but for the danger attending the use of considerable doses, mercury in some one of its forms might be a very satisfactory agent for combatting the pneumococcus, especially at the outset of the disease.

The *New York Medical Journal* for June and July, 1879, contains a very interesting report on the "sedative" dose of calomel, made to the Therapeutical Society of New York by Dr. Putnam Jacobi, secretary of the Committee on Antipyretics. It is a summary of the results of a collective investigation covering fifty cases in which large doses (20 to 60 grains) of calomel were given. Fourteen cases were of croupous pneumonia, all of them severe. Of these patients thirteen recovered and one died. This is a remarkable showing, and it is impossible to read the report and not yield to the conviction that in some of these cases the calomel turned the scale toward recovery. In no case was there excessive purging from so large a dose. Stomatitis occurred only twice in the fifty cases, and produced no serious inconvenience.

More recently Pieragnoli[2] strongly recommended the employment of calomel in croupous pneumonia. His method consisted in the daily administration of calomel combined with opium. His results were very satisfactory. Of five patients to whom the calomel was not given, all died; of fifteen who were treated with calomel all but one recovered. Equally good was the result in children. The course of the disease was milder, the infiltration was less firm, and the wandering of the disease in the lung less marked.

Smarkovsky[3] of Moscow claims that calomel given in doses of 5 or 6 cgm. (gr. 3/4-1) every hour until a purgative effect is produced, is capable of jugulating croupous pneumonia, and causing its abortion. This does not result, he observes, from any direct influence of the calomel upon the pulmonary lesion, but from a general antiseptic action upon the toxic material circulating in the blood, thus augmenting the resistance of the organism to the morbid local process.

Granting the major proposition in the sense intended, it would be more reasonable to infer that the drug acted toward limiting the production of the poison rather than its destruction after it had reached the current of the blood. And I wish to avail myself of this opportunity to place on record my disbelief in the power of any drug taken into the circulation to neutralize or oxydize or in any way act upon the toxic product of any micro-organism, and my belief that the benefit in all such cases is from acting directly upon the organism itself to prevent or to limit the further production of toxin, the system readily taking care of that already formed.*

Quinin, though a feeble antagonist to other than malarial germs, has sufficient power to impose a considerable check upon the activity of the pneumococcus. Flint, Loomis, and many other authorities bear witness to the benefit derived from large doses of the drug, which in their hands often lessened the severity of the disease and shortened its duration, sometimes even bringing about a complete abortion. We need not be surprised at this action of quinin when we consider how thoroughly it saturates the blood, and how it pervades every portion of the system. Flint says:[4] "As long ago as 1861 I was led by the results of the analysis of a considerable number of cases in which sulphate of quinin was given to the extent of only 15 grains daily, to the conclusion that this remedy exerted a marked curative influence on the disease. I can now (1881) bear testimony to the fact that, given in larger doses, namely, 20 to 30 grains daily, this remedy, in a certain proportion of cases, renders the disease abortive, and that when this does not follow, the disease is often modified to a greater degree than by smaller doses. Now, whatever efficacy belongs to these remedies proceeds evidently not from any direct effect upon the pulmonary affection, but from a controlling influence over the pyrexia, thus sustaining the doctrine that the disease is an essential fever."

How this abortion is to be effected simply by acting on the heat center there is no attempt to explain.

Hare[5] expresses the belief that quinin with aconite or veratrum viride, employed before consolidation has taken place, has the power of so modifying

* The proof of this is a matter of daily observation. When we wash out a septic uterus with simple plain water, or when we open up and drain an abscess, we get an immediate fall of temperature, although we have done nothing whatever to the blood. Strictly speaking, there is no such thing as *general* antisepsis. The action is always local, even though brought about through the medium of the circulation.

the hyperemia in the affected area as practically to abort the local process and prevent exudation. We must believe, however, that it is not so much by "modifying the hyperemia" as by acting directly upon the micrococcus that the abortion is brought about. I am not aware that the influence of quinin upon the diplococcus has ever been tested by direct laboratory experiment.

Clemens,[6] and subsequently Baumgarten, Oertel, and others derived great benefit from inhalations of chloroform in pneumonia. Dr. J. S. Thacher, at my suggestion, made some observations last year in the laboratory of the Presbyterian Hospital which showed that the pneumococcus was very sensitive to the influence of chloroform in the culture medium, thus giving the key to the clinical results obtained almost half a century before the specific germ was discovered.

Coming down to recent years,[7] Robinson and Kerr[8] are enthusiastic advocates of creosote both by the stomach and by inhalation. The pneumococcus, as we have already seen, is extremely vulnerable, and while it may not be actually killed by any vapor that could be safely taken into the lung, there is no reason why its growth should not be inhibited to a considerable extent, and the amount and virulence of the toxin materially lessened. It is no sufficient objection to this proposition that the inhaled material could not reach the air-cells of the hepatized area, since all goes to show that the most favorable conditions for general infection are supplied by the partly-filled alveoli surrounding the consolidated focus. To these cells a gaseous agent can easily penetrate.

As to the use of creosote by the mouth, we know in what large doses it is administered with safety in the treatment of tuberculosis. That it enters into the blood and reaches the lungs we have abundant evidence in the odor it imparts to the breath. A. H. Kerr says of it: "I do not say that it is a specific in pneumonia, but I do say, and with emphasis, that it is the nearest approach to one that has yet been reached. He gives the details of a case seen within twenty-four hours after the chill. The pulse was 120. Temperature 104.2° F. Respiration 40. Dulness and fine crepitant râles over the base of the left lung. Ten minims of creosote were given every two hours, and for the first day a grain of opium every three hours. The following day (the third of the disease) the pulse remained at 120, temperature 104° F., respiration 36. Twenty-four hours later (fourth day) pulse 96, temperature 102° F., respiration 26. At the next visit (fifth day) pulse 80, temperature 99° F., respiration normal, patient convalescent.

Under the head of "Note di Terapia"[9] the *Clinica Moderna* states that it has been demonstrated that clysters of creosote, each containing from twenty-five to forty drops, are of great value in pneumonia, and cause a subsidence of all alarming phenomena of the disease.

Van Zandt[10] (1898) advocates strongly the use of creosote either singly or in combination with ammonium salicylate, and reports a number of cases in which its use was followed by prompt defervescence in advance of the usual time of crisis.

In an inaugural thesis published last year, E. Corgier[11] discusses at length the properties of the carbonate of creosote which adapt it for use in acute pulmonary affections. He shows that it can be taken in large doses, up to a dram or more, without producing gastric irritation, and that, being slowly decomposed in the small intestine, it liberates the creosote in such a way as to keep the blood constantly charged with it even when the doses are separated by intervals of six, or even twelve, hours. Owing to this slow liberation poisonous effects are never developed with medicinal doses. [The occasional smoky urine does not imply disintegration of blood corpuscles, as at one time supposed, but is the result of a harmless chemical reaction and may be disregarded.] As in the case of creosote itself the drug is largely eliminated through the lungs, and the odor of creosote is quickly developed in the breath. The action is therefore double, first, in the blood within the tissues; second, as a vapor in contact with the pulmonary mucous membrane. These facts in connection with the powerful antiseptic quality of the remedy seem to fit it especially for use in acute pulmonary troubles. In this form too, it has the advantage of being comparatively tasteless, and therefore easy of administration.

In its effect upon the system at large the carbonate, called also creosotal, is an ether, and in so far as it is taken into the system in its combined state it acts as an ether. When broken up in the intestine into carbon dioxid and creosote the latter, which is an alcohol, acts like other alcohols as a cardiac and nerve stimulant. We have, therefore, in either case the reverse of the depressing effect which is a possible result of the use of many other powerful germicides and especially the salicylates.

For some time past the carbonate of creosote has been used extensively in the clinic of Dr. Cassoute of Marseilles, and this thesis of his pupil deals with material furnished by the clinic. Among other cases, it details three of lobar, and ten of bronchopneumonia, in which the carbonate of creosote was practically the only medicament employed. In every instance the effect upon the temperature was

most marked, defervescence being promptly effected in the cases of lobar pneumonia, while in the cases of bronchopneumonia the temperature was notably lowered and the severity and duration of the attack proportionately lessened.

The argument of Dr. Corgier is certainly a very strong one, for the selection of this as the most promising of the various medicaments yet brought forward for acting directly upon the toxic conditions present in pneumonia. The writer adopts the idea that the disease is primarily bacterial, and that we should attack the bacteria as the source of the toxin. But he speaks of pulmonary localization as if the general condition had preceded the local, and emphasizes the necessity for general as well as local antisepsis. He seems to consider the lung as the chief sufferer from a general infection, instead of the source of the infection from which the whole body is suffering.

Salicylates.—Robert Liegel[12] contributes a remarkable paper in which he describes a treatment which has been successful in his hands in seventy-two consecutive cases of croupous pneumonia occurring in the miners at Leoben Seegraben. The patients ranged from sixteen years of age to seventy-four, and included many subjects of anthracosis. Eight had pulmonary emphysema; six cardiac disease. A large proportion were alcoholics. The drug relied upon was sodium salicylate in "large doses," not less than 120 grs. daily. This was given in solution. No other medicine was employed, except perhaps an expectorant containing ipecac, if the cough was tight and racking, and small doses of morphin when pain was excessive. Ice was applied to the head when the temperature was above 39.5° C. (103° F.)

Under this treatment not only did recovery take place in every case, but the duration of the attack was diminished one-half. In no case did crisis occur. The temperature declined from the end of the first day, until at the end of three or four days it reached the normal, and convalescence was established. The expectoration lost its distinctive character and became catarrhal, the physical signs did not fully develop, or if present speedily retrogressed. The microscopical examination of the sputa showed a constantly diminishing number of diplococci, until, at the end of the third or fourth day, they were found to have entirely disappeared.

In the earlier cases the medicine was suspended as soon as the temperature became normal, but this was found in a number of instances to be followed by relapse; observing this, the doses thereafter were continued for some two or three days longer, and no further relapse occurred.

Previous to the adoption of this treatment the management of the disease by the usual methods had been unsatisfactory and the mortality excessive.

Liegel does not grasp the anti-bacterial idea but considers that the salicylate exerts a specific effect, such as it exhibits in rheumatic fever. He, however, assumes that it acts on the mucous membrane, increasing its secretion and thereby throwing off the exudate, as croupous membrane is thrown off from the larynx. In no instance did it give rise to any symptoms more unpleasant than a buzzing in the ears. Indeed, the dosage was fairly moderate, less than we habitually employ in the early stages of acute rheumatism, and anything like poisonous effects could scarcely be apprehended.

Liegel believes that this treatment will save nearly all cases, and he cites some instances to show that the most unfavorable conditions may be recovered from under its use. In one of these a man sixty-seven years of age was taken with pneumonia while living in a damp cellar in which six persons were huddled together. He had been insufficiently nourished before the attack, and when first visited was found delirious and too much prostrated to be removed to the hospital. He recovered, however, in the same time as the others, notwithstanding his miserable surroundings.

This is the latest and most important illustration of the possibility of so acting upon the blood as to hinder the growth of the bacteria, and to diminish, if not prevent, the formation of toxin.

The following is from a private letter to me, from Dr. A. Ross Matheson, of Brooklyn. The substitution of the ammonium salicylate for the sodium salt has much to recommend it, but the latter has seemed to me to be better borne by the stomach:

"For several years I have used the salicylate of ammonium in pneumonia, more especially in those cases occurring during the grip season and in which there was a grip element more or less pronounced. I am now treating a case of lobar pneumonia in the third stage in which the only remedies administered have been salicylate of ammonia, codein sulphate, and strychnin sulphate. The symptoms in this case in the beginning were formidable in the extreme, but modified early as a result, I believe, of the effects of the ammonium salicylate. I administer it in ten to fifteen grain doses, and endeavor to have the patient take from one and a half to two drams in twenty-four hours.

"I find that ammonium salicylate has some advantages over the soda salt. It is stimulating, while the latter is more or less depressing, and it does not produce to the same extent the throat and ear disturbances. I am satisfied that it has decided value."

Dr. J. H. Ferguson, of Mine La Motte, Mo., informs me that he has records of one hundred and six cases of pneumonia treated by him with sodium salicylate, showing one hundred recoveries and six deaths. He was led to this method by the belief that inflammation in general was intensified by uricacidemia. He gives five grains every two hours, together with potassium citrate, to stimulate the kidneys.

In concluding the argument for a treatment addressed to the bacteria themselves, I will say a word as to the time at which such treatment is to be instituted. Emphatically at the earliest possible moment. If we had the patient constantly under our eye and began treatment the instant we even suspected that pneumonia *might* be impending, we should even then, as I believe, often find that the diplococcus had already effected a lodgment and the local process was already under way. The occurrence of the chill is a certain indication that a considerable amount of toxin has been formed in the lung and taken into the general circulation. Every hour fills up more air-cells with the exudate and shuts them off from communication with the functional circulation upon which we are to depend to carry our remedial agent to the field of its activity. In every cell so shut off the germ culture will go on until arrested by exhaustion of the medium or other natural processes which it would carry us too far to discuss.

But even if we miss the auspicious moment, so long as the disease is spreading we shall still be in time so to act upon the zone just outside of the consolidated area. And it is precisely here that the most active mischief will always be going on. It is the young, newly formed cocci that are virulent, the older ones in the centre of the focus are relatively harmless. This has been proved by laboratory cultures. And it is the half-filled cells in whose walls the functional blood is still flowing that afford the best chance for absorption of the toxin. There is, therefore, no moment while the local disease is advancing when we may not expect to lessen in some degrees the flood of toxin being poured into the general circulation

As long, therefore, as persistent temperature and pulse frequency show continued formation of toxin, so long effort to combat this formation is demanded. The earlier instituted the better, but it is never too late to begin.

In my view it is the duty of the family physician to provide his families with either creosotal or one of the salicylates, and to instruct them that with the slightest chilly sensation or the slightest stabbing pain in in the lung a dose is to be given at once and that this dose is to be repeated at stated intervals until the physician arrives. This might prevent the development of pneumonia in some cases and shorten the attack in others.

My individual experience with the line of treatment in question, though not large has been encouraging. The cases coming under my observation are for the most part in an advanced stage of the disease, and often in a well-nigh hopeless condition. Yet even in such cases I have seen, or thought I saw, marked benefit from the antigermic means employed. I have been searching for the best weapon against the pneumococcus. I have used all of those I have mentioned this evening, with the exception of large doses of quinin, which have seemed to me too slow in action and too disturbing to the stomach. At one time the salicylates were my preference, but I think that late in the disease they may be depressing to the heart, and they often cause a good deal of gastric irritation. I now prefer carbonate of creosote. In my hands it has done good service, and the testimony of many authorities, as we have seen, is strongly in its favor. So far no inconvenience seems to have resulted from its use.

As to accessory treatment, I shall say but little. It comprises, first, stimulation of the emunctories to carry off the poison as it forms; second, sustaining the vital powers and particularly the heart-cardiac stimulants, hydrotherapy; third, relieving the pulmonary circulation — vasodilators, venesection; fourth, compensation for loss of respiratory surface— inhalations of oxygen; fifth, reduction of excessive temperature—cold to surface, antipyretics (?); sixth, relief of incidental symptoms.

There is only one point under this head that I care to insist on at this time. When the chief danger to life is mechanical, *i.e.*, from obstruction to respiration, and there are cyanosis and distention of the veins, and frequent, rattling respiration, I would give arterial dilators, and I would not give digitalis. In my experience blueness and digitalis go hand in hand. If we can keep our patient's face florid we may have hope for him; but blue lips and ashen cheeks are the shadow of death. If we can retain a portion of the blood in the arteries instead of driving it all into the veins, the right heart will thank us, and we need not apologize to our sphygmograph for neglecting its warning. I infinitely prefer a big pulse, however soft and gaseous, to a tiny thread that the finger can scarcely discover. As to the pulse *under these conditions* becoming slower and fuller from the effects of digitalis, it is a phenomenon I have never witnessed. And this leads me to devote a moment to the treatment advocated by Petrescu of Bucharest which he claims saves all but two per cent. of his cases, and to which the friends of digi-

talis so confidently appeal. His statistics are good, but all his patients are young soldiers, picked men, who have passed a rigid physical examination. He has them constantly under his eye, and at the first sign of illness they are taken into the hospital and placed under treatment. But if his patients included both sexes and all ages, if he had to deal with a full proportion of alcoholics and nephritics and diabetics and cardiac incompetents, with half-starved beggars, and gouty dyspeptics, and if they were trundled from a distance to the hospital at no matter what stage of the disease, and with no matter what previous treatment, his ratio of cures would be considerably different. Moreover, the watery effusion of digitalis which he employs does not represent the drug, as it contains almost no digitalin but depends for its efficacy upon digitalein and digitonin. Indeed I would hazard the conjecture that the enormous doses of this preparation administered by Petrescu do quite as much by poisoning the pneumococcus as by acting on the heart and arteries.

The serum treatment of pneumonia from which so much has been expected, has not yet yielded any definite results. Still there is enough to encourage further effort, and it may be that in the near future an important addition to our resources will be attained, and that we shall have an antitoxin as efficacious in pneumonia as is the one we now have in diphtheria.

In the discussion of this subject I have for lack of time purposely omitted many interesting points in pathology which have not a direct bearing upon treatment. My wish has been to fix attention upon the point at which the pathology and the treatment of pneumonia come into touch one with the other. If this point can be made to broaden into the basis of a rational therapeusis my aim will have been accomplished.

THE EXPLORATION OF THE ABDOMEN AS AN ADJUNCT TO EVERY CELIOTOMY.

BY HOWARD A. KELLY, M.D.,
OF BALTIMORE.

I HAD occasion in several instances some sixteen years ago, to make post-morten examinations and to remove through an opening in the vaginal vault in women, and through the perineum and through the rectum in men various viscera which I was desirous of inspecting.[1] I was enabled in this way to secure specimens not only from any part of the abdominal cavity, but by perforating the diaphragm, from the thorax as well, removing in one instance both heart and lungs. I recall with particular distinctness my first case, a woman with large white kidneys whose history I had followed with unusual interest, and where I had reason to feel assured I would be refused the privilege of an autopsy by the unintelligent relatives, abetted by the undertaker. I was in this instance able to remove both kidneys through the vault of the vagina without leaving any external evidence whatever of the depredation committed.

I cite these cases, not without considerable misgivings as to the propriety of my conduct in thus stealing an autopsy, in order to show how easy it is to reach all the various viscera through an incision as far as possible from the center of the abdomen, large enough to admit the forearm, as well as to urge the propriety, or rather the necessity of making a somewhat analogous investigation of all the abdominal viscera every time the abdomen is opened in the living subject.

Although I had not infrequently made such examinations from the earliest years of my work, in common I suppose with other surgeons I was led to adopt the investigation of the abdominal and pelvic organs as a routine plan to be followed in all celiotomies by the following circumstance which caused me no little chagrin. I was treating a woman for pelvic peritonitis with adhesions binding down both tubes and ovaries; I first broke up the adhesions under anesthesia, and then, finding that she continued unrelieved, in December, 1894, I opened the abdomen, brought the adherent tubes and ovaries up out of the incision, carefully freed all adhesions and returned the now fairly normal organs, and finished by suspending the retroflexed uterus.

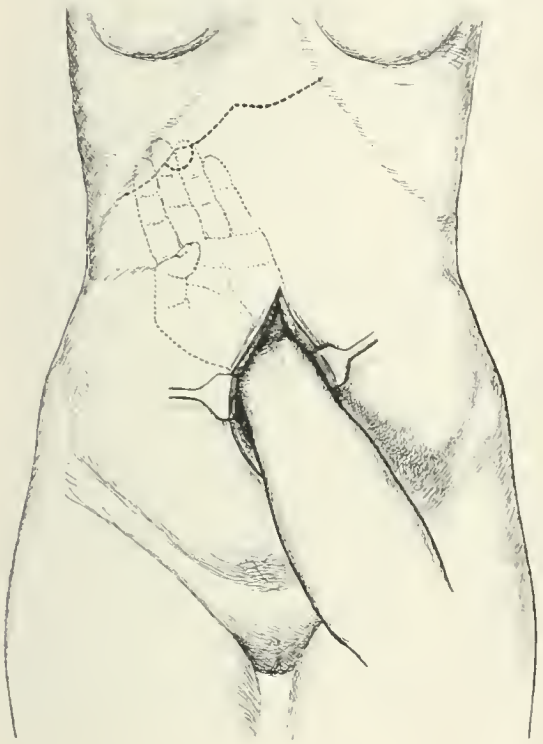
She passed entirely out of my hands and I did not hear from her again further than to realize that the success of my work was but a qualified one, until a

[1] A method of post-mortem examination of the thoracic and abdominal viscera through vagina, perineum and rectum, without incision of the abdominal parietes.—MEDICAL NEWS, June 30, 1883

number of months had elapsed, when she wrote from a distant point saying that she had undergone an operation for chronic appendicitis by which she had been entirely relieved, and that she was convinced that this had been the real cause of all her discomforts as well as of the pelvic inflammation which I had been treating.

Whether the reproach was deserved in this case I have had no means since then of deciding, but I acted upon the assumption that I was blamable for neglect and took the lesson to heart, and have ever since that date inspected the vermiform appendix in every instance in which I have made an abdominal

Fig. 1.



Method of exploring the abdominal viscera.

incision large enough to permit such an examination, and have recorded its condition in writing on a slip kept by the anesthetizer during the operation; furthermore, realizing that not only the appendix might be at fault but some other abdominal viscus as well, I have made a systematic examination of the entire peritoneal cavity in every instance in which the condition of the patient did not forbid it.

It will, I am sure, be easy for any surgeon to whom this proposition is presented for the first time, upon pausing to consider the matter to adduce shortly a number of excellent reasons why such a practice should sometimes prove serviceable; let us consider some of them.

In the first place, abdominal diseases of all kinds are commonest in middle life, the period when most of our celiotomies are performed and it becomes practically certain, reasoning simply from the law of chances, that a coincidence of two or more entirely independent diseases is sure by means of this examination to be discovered occasionally.

In the second place, there is a constant association between certain abdominal surgical affections and affections elsewhere in the form of a mutual interdependence, whether from the propagation of a disease from a central point, as in the case of cancer, sarcoma and tuberculosis, or from a mechanical action, where the effects of pressure are manifested near to or at a distance from the seat of the disease, as in the case of pelvic tumors or inflammation obstructing the vascular, the urinary or the alimentary channels.

In the third place, such an examination if negative gives both operator and patient a comfortable assurance that the convalescence will progress without interruption, as well as the satisfaction of realizing that there is no visceral affection in progress which is liable in the near future to shorten life or to impair health.

The following diseases are most likely to be found in such a routine examination: appendicitis, hernia, either inguinal, femoral, or umbilical, hydro-ureter, disease of the omentum, pyloric cancer, movable kidney, enteroptosis, cancer of the liver, perihepatitis, gall-stones.

In making an investigation, or rather in taking an inventory of the abdominal cavity in this way, certain of the organs can be inspected as well as handled, while others can only be felt. The range of vision is limited to the area adjacent to the incision and those structures which can be drawn over into the neighborhood of the incision; the field is of course extended by enlarging the incision. In a lax or scaphoid abdomen where the reserve space is large, the abdominal walls may sometimes be hooked up well away from the viscera, which can be seen by stooping down and looking in or by inserting one of my largest calibre rectal specula and using a headlight. This extension of the field of inspection is also often feasible after removing a large ovarian or a large fibroid tumor.

There are four steps in the exploration of the abdomen:

First, the simple inspection of such structures as can be seen in the neighborhood of the incision by drawing the lips of the incision widely apart.

Second, the examination of those structures which can be brought into view by inserting two fingers through a small incision and catching structures near

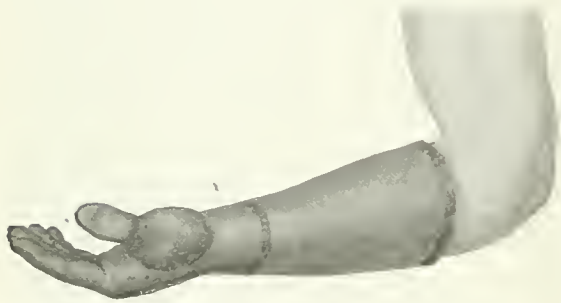
by, such as ovaries, tubes, cecum and appendix, as well as uterus.

Third, by the insertion of the hand as far as the wrist, by which the colon and the stomach and the pylorus can be grasped and palpated or pulled down, and

Fourth, by the insertion of the forearm in order to reach the liver, the gall-bladder, the kidneys and the spleen.

The technique of such an exploration is this: extreme care must be taken to maintain asepsis by thoroughly sterilizing the arm or by wearing a rubber glove with a long sleeve reaching as far as the elbow, which I have had made for this particular purpose. (See fig. 2.) If the field of the operation, that is to say the area in the immediate neighborhood of the incision, is so septic as to demand the use of drainage, then the operator would best forego the advantage of the more extended examination on account of the risk of distributing the septic material.

Fig. 2.



Rubber gauntlet.

The length of incision necessary for a complete exploration of the abdomen must vary from ten or twelve centimeters up to fifteen (6 to 9 inches) according to the size of the operator's forearm; it must be so large that he runs no risk of bruising the tissues by forcing in the arm through a tight opening.

The best posture in which to examine the patient is either lying flat on the table, or with the pelvis slightly elevated; a decided elevation often causes the appendix to gravitate up out of reach for inspection unless one uses dangerous traction on the cecum to bring it down.

The various structures are examined in an order which must vary with the location of the incision; when the abdominal opening is made low down over the middle of the pelvis, I commonly follow some such routine as this; after carefully noting the condition of each pelvic viscus, uterus, tubes, ovaries, bladder and rectum, I then look at the internal inguinal rings, locating them if necessary by the round ligaments, and test them with the index finger to see if there exists a hernia, and if so I proceed to sew it up at once from the inside of the abdomen, first passing the needle through the outer pillar of the ring and then through the inner, using one or two mattress sutures of silk; another row of sutures draws the peritoneum over the first line so as to bury them; in this way the hernia is closed from the inside, the side on which the pressure falls first and, therefore, in the position of the greatest mechanical advantage.

The umbilical ring is next examined, and if there is an opening it must be closed in like manner from the inside with one or two mattress sutures. The bladder is then examined for adhesions, which are often found on its peritoneal surface. The rectum also will often be found involved in a pelvic peritonitis, especially near the pelvic floor.

The next point of importance is the vermiform appendix, for which the pelvis ought not be elevated at all. Unless the abdominal walls are thin, the incision must be larger than that used for suspension of the uterus by my method, that is to say over 4 or 5 cm. in length. The cecum can be best caught and drawn into a small incision by grasping the bowel in the right iliac fossa by the last phalanges of the index and middle fingers, between the dorsal surface of the index and the palmar surface of the middle; in this way the appendix can be brought into view when the incision is only large enough to admit two fingers.

The cecum secured and brought out, the appendix is traced by following the anterior band of longitudinal muscular fibers, and when found it should be removed if it shows any traces of previous inflammation. In a series of 115 cases in which the condition of the appendix was noted at the operation, it was found adhering to the right tube or ovary in 10 cases, in 37 cases it was involved in adhesions, it was congested in 3 cases, and obliterated at the cecal end in 1 case. Only 64 appendices were perfectly normal.

In a series of 200 abdominal sections I have had occasion to remove the appendix 25 times.

The routine inspection of the ureters in gynecological operations is perhaps as important as that of any other abdominal organ after the appendix, and for this reason every surgeon should be thoroughly familiar with the ureteral landmarks. The best place to find the ureters is where they lie upon the common iliac arteries at the pelvic brim; on the right side the ureter may be seen, upon lifting up the inner border of the cecum, crossing the brim with the ovarian vessels. If watched for a little while a peristaltic wavelet, at once establishing its identity beyond a doubt, will be seen traveling down toward the bladder. On the left side it is necessary to

draw the sigmoid flexure in the same direction, that is to say, toward the median line, in order to affect a similar exposure. In cases of carcinoma and myoma uteri and ovarian cysts such an examination will often reveal the presence of a hydro-ureter, in suppurative pelvic affections a pyo-ureter may be found.

A case which I operated on in Paterson, New Jersey, at the request of Dr. J. C. McCoy, serves beautifully to illustrate the point I wish to make here. The patient had a fibroid uterus reaching as high as the umbilicus, and altogether about as large as a six-months' pregnancy. I removed it by my method of supravaginal amputation, cutting from left to right. I then examined the adjacent structures and found the appendix bound down by adhesions in the pelvis and removed it. Then after stating to a number of gentlemen who were present, the importance of examining the ureters also in such cases, I proceeded to investigate carefully and found on the right side an extensive pyo-ureter leading up to a pyonephrosis, whose presence there had been no clinical reason whatever to suspect.

I accounted for the pyonephrosis in the following manner: the myomatous uterus which filled the pelvis had backed up the urine by pressure at the brim causing a hydro-ureter and a hydronephrosis, then came the appendicitis adding the element of infection conveyed through the tip of the appendix which I found firmly soldered down in the pelvis upon the ureter about 4 cm. below the brim of the pelvis.

Dr. McCoy at a later date removed the right kidney, completely curing the patient. By making a routine examination of and discovering the complication at the first operation, I saved myself the possible, and I think proper, imputation of having ligated the ureter, and so of having caused the pyelonephrosis, I furthermore made an accurate diagnosis as to the presence and location of the complication and determined that the opposite side was unaffected, so making the subsequent operation a safe instead of a hazardous undertaking.

The position of the transverse colon and the stomach are to be noted on account of the frequency of enteroptosis.

Up to this point it has only been necessary to introduce the hand as far as the wrist, it now becomes necessary to introduce the forearm, and for this purpose the edges of the incision are protected with gauze, and the omentum held down while the hand is pushed in, in front of it, with fingers extended and thumb pressed into the palm so as to take up less space. Whichever hand the operator uses he should stand on the corresponding side of the patient and push the hand first back into one flank and then into the other and thus palpate both the kidneys, noting their presence, size, form, and mobility by sliding them up and down. The renal pelvis may be felt and inverted towards the calices to detect a stone. After the kidneys, the liver is felt, its apparent size, the regularity of its surface, its margin, any adhesions which when present indicate perihepatitis. Most of all, the superior viscera the gall-bladder is next located by feeling the fissure between the right and left lobes of the liver and then palpating across the lobus quadratus to the depression on its right side where the gall-bladder is found, as a rule, well distended.

By taking it between the thumb and two fingers and squeezing it with moderate force, a healthy gall-bladder collapses slowly as the bile is forced out into the hepatic and common ducts. Not infrequently on recovering from the anesthetic such a patient vomits at once a quantity of golden-yellow bile. When the gall-bladder is collapsed one can then readily feel a stone if it be present, by pressing its walls together.

I next put my index-finger in the foramen of Winslow, easily found below the gall-bladder, and palpate the hepaticoduodenal ligament and trace the common duct down for several centimeters, feeling for a stone there. The spleen may then be felt, taking the stomach as a guide.

Finally the pancreas is found by carrying the hand in under the omentum and palpating through the transverse mesocolon.

The aorta may be palpated thoughout the entire length of its abdominal portion by pressing the fingers back against the vertebral column as the hand is withdrawn.

In a case of Dr. G. P. Yost's, in which a patient convalescent from typhoid fever was suddenly seized with severe pains, marked elevation of temperature, and had a decided distention of the abdomen, there was reason to suspect an attack of acute appendicitis or perforation of the intestine. In this instance I made an incision just inside the anterior superior spine of the ilium, and finding the bowel and appendix normal but the peritoneum everywhere in a state of subacute inflammation, and the abdominal cavity full of a dark thickish fluid, I explored the rest of the abdomen through the incision and was rewarded by finding a gall-stone in the bladder. A close examination of the fluid showed that it was probably bile, and the diagnosis of ruptured gall-bladder following typhoid fever was therefore made and the abdomen opened above, the stone removed and the gall bladder drained and the patient recovered.

In another instance in which the patient located her pains under the liver and there was every rea-

son to suspect the presence of gall-stones, upon finding none I palpated all of the abdominal viscera through the incision made in the linea semilunaris just below the ribs and found far down on the pelvic floor a large hematoma of the left ovary which was at once removed by a suprapubic incision.

I shall not pause to cite cases in which isolated carcinomatous nodules have been found upon carefully searching through the omentum, or enlarged mesenteric glands in peritoneal tuberculosis; or in other cases in which a carcinomatous infiltration has been discovered in the pylorus or nodules in the liver, in each instance materially affecting the prognosis as to complete recovery.

In cases liable to metastasis, such as those just cited, it is my practice to reverse the order of the investigation wherever possible, making the exploration of the abdominal viscera first and then doing the operation. If I find a metastasis which is out of the reach of surgery, I would not then feel justified in taking the same risks in removing say an advanced carcinoma in the pelvis.

In conclusion let me recapitulate and restate the points I desire to emphasize presenting them from a slightly different standpoint.

The important lesson I wish to inculcate is that, provided an incision has been made in the abdominal parieties large enough to admit the entire hand and therefore the forearm, it is always an advantage to the patient to be able to assure him that as far as touch could ascertain there is no disease of any other abdominal organ.

Under some circumstances where there is reason to suspect disease of one of the other viscera not in the proximity of the field of operation, I would make a larger incision than necessary for the performance of the operation for the very purpose of making such an exploration.

There are in general three classes of cases to which this extended examination may be applied:

Firstly, those in which there has been no reason to anticipate any disease of any other organ and the examination is made simply as a routine procedure, whenever it adds nothing to the gravity of the situation. In such cases we are most liable to find unsuspected hydro-ureter, appendicitis, movable kidney, gall-stones, and occasionally pyloric tumor.

Secondly, those cases in which on opening the abdomen, contrary to expectation no disease is found near at hand. The operator may then find it of great advantage to enlarge the incision, introduce the hand and the forearm and explore the entire abdomen. I have cited a case of this sort in which I made an incision over the appendix and finding no appendicitis, enlarged the opening and found a gall-stone within a ruptured gall-bladder; also, another case in which gall-stones were believed to be present, but in finding the diagnosis at fault I introduced my arm through the enlarged incision and found a large hematoma of the ovary.

Thirdly, the group of cases in which there is a definite percentage of chances that the disease discovered at the time of operation is complicated by the affection of some other organ neighboring or remote. In cancer of the ovary I examine all the organs and in no small percentage of cases have the disappointment of finding metastases in the omentum pylorus, or liver. In pelvic inflammatory disease the appendix will be frequently found involved, and in the case of pelvic tumors as well as inflammation the ureters are prone to suffer from compression.

NEURASTHENIA; ITS SYMPTOMS AND TREATMENT.

By LANDON CARTER GRAY, M.D.,
OF NEW YORK.

NEURASTHENIA is best described by its English synonym, nervous prostration. Just as many functions as there are of the nervous system, just so many functions may you have depressed. The attempt has been made to differentiate a spinal and a cerebral form, but this is almost impossible, although there may be a predominance of either cerebral or spinal symptoms. The various functions of the mind are performed imperfectly, and there is a lessened capacity for mental work in all its myriad forms, whilst the lower and less conscious functions of the spinal cord also suffer. The symptoms, however, are rather those of impairment of function than of perversion. For instance, thought is correct, but cannot be sustained as long as in health; attention can be given, but not equally well; the memory does not suffer; the mood is but slightly altered, except by occasionally brooding on the illness there being no hallucinations, delusions, or illusions; this slight alteration of the mood differing radically from the profound melancholy of melancholia, with its delusions and suicidal impulses, or the feverish excitement of mania, or the fixed delusions of persecution and self-exaltation of paranoia, or the glittering perversions of the senses in hallucinatory insanity, or the stupid delusions of grandeur of general paresis. A neurasthenic may be nervous, or, if one chooses to call it so, hysterical, but only as a result of the neurasthenia. The worn or haggard countenance and the inability to support fatigue are seen by the competent eye to be due to nervous weakness and not to *nervousness*, although the nervous weakness may in its turn produce nervousness—a fine yet very important distinction.

Neurasthenia may be caused by over-work, mental or physical, or by great emotions; by such diseases as typhoid or other fevers, influenza, indigestion, nephritis, diabetes, syphilis, tuberculosis, rheumatism, gout, anemia, lead, hysteria, palmus, or chorea; by intestinal, cardiac, nasopharyngeal, genital, or pulmonary lesions; by such vicious habits as masturbation, or the use of alcohol, cocain, morphin, absinthe, tobacco, tea, and coffee; and occasionally even by errors of refraction. At first sight it would seem as if this were a very formidable list of causes to remember in examining a case; but practically it is very easy. It should be the rule to make a urinary examination, and thereby determine the presence or absence of albumin or sugar. It must be distinctly borne in mind that small quantities of albumin or sugar, or both, or a few hyalin casts, are not evidence of renal disease but may be simply indicative of neurasthenic conditions; so that a nephritis must be sought for by means of a suspicious persistent specific gravity and continuous hyalin, granular, epithelial, or fatty casts, or by the evidence of arterial or cardiac alteration in conjunction with these. Contrary to the general belief, uric acid may be disregarded in its relation to neurasthenia. The older theory of Murchison has been discarded, and instead of regarding uric acid as a product of suboxidation, it is now known to have its origin in the nuclein of cells, not of those composing the fixed tissues of the body, except to a very slight degree, but of the food-cells and the motile body-cells, and whether it is excessive in amount is a matter of very delicate chemical examination. This matter is of very little importance clinically for the theories of Haig are accepted by few chemists. Nevertheless, there is a condition answering to what we call lithemia, more largely to be diagnosed by the symptoms than by the chemistry, however obscure the pathology and treatment may be. Having examined the urine, the heart should be investigated, and the history will decide whether it is necessary to examine any other viscus, or whether the patient has suffered from any other of the possible causes. A sharp distinction, however, must always be made between cause and effect, and it must be remembered that while a cause may be removed, the effect may yet continue. Simple as this proposition seems, it is very seldom that the physician obtains an adequate mental concept of it. To illustrate: suppose I light a match and set fire to a piece of paper. The lighted match is the cause and the burning paper is the effect. Now, I blow out the match and remove the cause, and yet the effect, the burning paper, continues and has to be itself treated. In this way these different causes which have been enumerated may set up neurasthenia, and yet when they are removed, the neurasthenia, the effect, will persist and will have to be treated—indeed, in many cases the cause and the effect will have to be treated together.

Neurasthenia must be differentiated from melancholia, hysteria, general paresis, bromism, locomotor ataxia in its early stage, and hypochondria.

Melancholia is characterized by obstinate insomnia, by some curious sensations, as a pressure, a creeping ache up or down or actual pain in the back of the head and neck, sometimes running far down the spine, and sometimes as far up as the vertex of the skull; by a characteristically melancholic *facies*, nervous and melancholy agitation, or absolute silence, with or without cataleptic symptoms. None of these symptom-groups are present in neurasthenia.

The hysteric may have a hemianesthesia, *i. e.*, an impaired sensation of pain, touch, hearing, smell, or taste on one side of the body, or a paralysis involving only one limb (monoplegia), or hysterical convulsions—symptoms never observed in neurasthenia. In cases of hysteria of a less marked type there is no real physical depression, but immediate response to some suggestion or some placebo in the way of treatment. In both hysteria and neurasthenia there may be a tremor which, in the hysteric may be overcome by suggestion, but which is much slower to improve in the neurasthenic.

In general paresis there is a marked stupidity, either occasionally or continuously, a tremor of the tongue and facial muscles, lost or unequal knee-jerks, unequal pupils, and occasional days when the patient is flushed, has a staggering gait, and is more stupid, and has stupid delusions, generally of some exalted type. No case of neurasthenia ever has these symptoms.

Bromism is usually detected by the stupidity, peculiar fetid breath and the widely dilated pupils.

The early stage of locomotor ataxia will have lost knee-jerks, lightning-like or stabbing pains, seldom repeated in the the same place, and usually severe in character; and with these is often associated some difficulty in micturition or there may be distinct incoordination.

The hypochondriac is manifestly an exaggerator and his symptoms are palpably unreal.

The prognosis of neurasthenia is usually excellent provided the cause is removable. For this reason the favorable forms are those which are caused by over-work, mental or physical, by great emotions, or by influenza, the exhaustive fevers, indigestion, anemia, and hysteria. The prognosis of the nephritic, intestinal, cardiac, nasopharyngeal and pulmonary cases will depend entirely upon the degree and fixity of the lesions. Those proceeding from

syphilis usually respond very well to treatment, and the rheumatic and gouty forms are generally of good outlook. The choreic variety is extremely treatable, whilst that from palmus is of variable prognosis, some cases reponding readily, and others not. The forms resulting from vicious habits are perfectly treatable if patients can be controlled in their vices.

The treatment consists of: (1) removal or amelioration of the cause; (2) rest; (3) suitable physical and mental tonics, and (4) electricity. Simple as this enumeration is, however, the daily application of the principles from person to person is difficult, and it is made doubly so because a prolonged nervous depression diminishes the good sense and increases the bad judgment and lack of self-control.

The cause should, of course, be removed or ameliorated, if this can be done without aggravation of the neurasthenia. It is often a matter of extremely nice judgment to determine how much a patient can endure in the removal of the cause; for example, if the neurasthenia be profound, a dangerous operation should be deferred until the strength is greater. Rest should be both mental and physical, and its degree must be proportioned to the needs of the individual, so that little is given in a very mild case, whilst a severe one has absolute repose in bed. The recognition by Dr. Weir Mitchell of rest as the key-note of treatment in these cases was a stroke of genius, but the rough and ready application of it, since the popularization of the idea with the profession and laity, has often been appalling. It is seldom necessary to put patients to bed for three to six weeks, as was at first proposed. As a rule, it will suffice to keep them there ten or twelve hours out of the twenty-four, and to have them avoid fatigue when they are up.

The tonics to be used will vary somewhat. If there is anemia, iron should be employed, but if the neurasthenia is severe and the anemia profound, iron alone will not begin to do the work. In such a case, it will be found that dialysed iron ℥ i to ℥ ss three times a day, after meals, in a full tumbler of water, will be the best form, or, if the stomach is in any way susceptible, a peptomanganate of iron, a dessertspoonful three times a day, after meals, in a wineglass of milk. But with these should be combined tonic doses of sulphate of quinin, 2 to 3 grains, three or four times in the twenty-four hours, provided the patient has no idiosyncrasy about the drug. In some cases it will even be well to combine sulphate of strychnin with the iron and quinin, and in such circumstances the following prescription may be employed:

℞ Strych. sulph. . . . . gr. $\frac{1}{30}$
Ferri sulph. . . . . gr. ii.
Quin. sulph. . . . . gr. ii.
Ft. in pil. (argent) seu capsul. No. I. Mitte XV.

M. S. Three times daily one hour and a half after meals.

With these tonics, in severe cases, must be given a large amount of beef, and, inasmuch as anemics are, with a curious contrariety of nature, often extremely averse to taking it in the solid form, beef-tea should be employed.[1] No profound case of anemic neurasthenia will be relieved entirely without the iron, the quinin, possibly the strychnin and the overfeeding with nitrogenized matter, besides which these anemics need an unusual amount of fresh air, probably because of the deficiency in hemoglobin. A moderate degree of anemia, however, will not require this proportion of nitrogenized food, nor the large amount of iron, and it may even be hurt by the quinin, and in such cases it will be found well to employ ferratin and strychnin, in the following prescription:—

℞ Ferratin . . . . . gr. iii.
Strych. sulph. . . . . gr. $\frac{1}{30}$
Ft. in capsul. No. I. Mitte XV.
S. One three times a day just after meals.

If the patient is not anemic, the tonics that should be used will depend largely on the degree of the neurasthenia and the idiosyncrasy of the patient. If it is a mild case, an elixir of calisaya may be employed, a dessertspoonful before or after meals as may seem best. Some, however, can not tolerate this, and then it will be found well to give arsenic, either 3 drops of Fowler's solution, three times a day just after meals, in a full wineglass of water, or a tablet triturate of arsenious acid, $\frac{1}{100}$ of a grain, three times a day just after meals. Usually, however, the best tonic in the non-anemic cases is the sulphate of strychnin, in beginning doses of $\frac{1}{50}$ of a grain, three times a day, and increasing to $\frac{1}{30}$ of a grain. But where the patients have been put to bed or made to rest a great deal it is better to reserve this until they are beginning to get about more, although, in the case of business men who

[1] The best preparation of this is one made according to an old formula that extracts the albumen from the meat fiber, instead of, as in the usual method, leaving it behind in the stock that is thrown away, and giving the patient only the salts of the blood. Chop up fine one pound of good beef, preferably the tenderloin, put it into a bottle with one pint of water, and add 5 drops of the stronger muriatic acid, taking care to use a dropper so as not to burn the fingers. Then cork the bottle tightly, and put it upon ice for 12 hours. Then lay it, still tightly stoppered, sideways in a pan of water, so that the latter shall cover it. Put it on the back of the range for two hours, and keep the water at a temperature of about 112° F. Any apothecary's shop will supply a cheap thermometer which need be only approximately correct. Then strain the beef-tea through a piece of cheese-cloth, and the result will be a thick, curdly mass, rich in albumen, about three cupfuls in quantity. Before being given to the patient, it should be seasoned and cooked just as any soup is, and a cupful should be given three times a day, at or between meals.

are simply made to expend less energy in their affairs, the drug should be employed from the first.

In cases with a gouty history, the use of colchicum is necessary, and often will be surprisingly beneficial, either in the ordinary doses continued for several days, or, in slighter cases, 20 drops of the tincture of the root at bedtime.

The treatment of the lithemic cases has been a grave puzzle from the fact that the pathology is so imperfectly understood. When there can be no doubt, however, that the seeming lithemic trouble does not arise from indigestion or constipation, the lithiated waters should, as a rule, be employed in abundance, or Vichy, or Giesshuebler, giving from four to six glasses of each in the twenty-four hours. Some have found the glycerophosphate of lime, recently advocated in France, of great use in some of these cases given in doses of from 5 to 10 grains, three times a day. If any of the various forms of indigestion are associated they can usually be handled by the simple general plan of treatment of the neurasthenia, modified only to this degree, that the patient shall at the outset be put to bed absolutely for a month or six weeks, and that Mitchell's plan of beginning the dietetics with milk shall be adopted, viz., for the first twenty-four hours ℥ ii of milk every two hours, to be increased the second day to ℥ iv, and so on until two quarts are taken in the twenty-four hours, the following day a light breakfast should be added, the second day a light noon-day meal, the third, a light supper, so that at the end of two weeks the patient takes two quarts of milk and three full hearty meals in the twenty-four hours. With the simpler cases it will suffice to give the essence of pepsine, one teaspoonful immediately after meals, and a teaspoonful of the diastasic essence of pancreas one hour after; later it may be necessary to add a bitter tonic.

Of course the treatment just outlined is adapted to the functional indigestions only, and great care must be taken to exclude any organic trouble. In neurasthenia there is no true insomnia requiring hypnotics, and when there is any symptom of this kind not to be overcome by the general treatment, the case is probably one of melancholia, as a careful analysis will show.

Mental diversion is highly important, so far as it is otherwise consistent with the proper treatment of the ease, but no more cruel mistake has ever been made in medicine than that of driving exhausted neurasthenics into amusements which they are not only too wretched to enjoy, but which actually aggravate their symptoms, for it should always be fully realized that fatigue must be avoided as if it were a poison. In this connection, it will not be amiss to bear in mind that the organism must be accustomed to do only what it actually can do, and not what the patient thinks, judging from a former condition of health, that he should do.

Electricity is of great value as a therapeutic measure, and the lack of success with it has often been due to lack of precision in the *technique*. Good portable batteries, galvanic and faradic, can now be purchased at very little expense. The former should always have a competent meter and a regulator, or rheostat. The electrodes, or handles, should always be of a good malleable copper, so that they can be bent, having long, strong handles and being covered with absorbent cotton whose edges should be stitched together, back and forth, on the upper side. The skin and electrodes should always be wet with warm water before the electricity is applied, not with salt and water, as this corrodes the metal and roughens the skin. To give a galvanic current through the brain, one electrode, measuring 5 x 2½ in., should be put on the forehead, another on the nape of the neck, measuring 7 x 2½ in., and held gently but firmly in place; then the current should be slowly turned on by the regulator until two milliamperes are measured off on the meter, so gently that no flash of light will be perceived by the patient. The sitting should continue at first two minutes, and, later on, five, and then the current should be as gently withdrawn. For the spinal cord the electrode should be placed at the nape of the neck, as first described, and the other, measuring 6 x 4⅛ in., across the lower dorsal spine, skin and electrode being wet with warm water as before, and the current, first of five and then of ten milliamperes, should be turned on gently, continued for five or ten minutes, and then as gently withdrawn.

There is no tonic that will be as effective as this electrical treatment, properly and carefully given from day to day. In addition to this, general faradization of the muscles of the body is of great use, but it is not necessary, and should be employed only with patients who are careless of expense and time.

Massage is often a great aid, but not always. There are some people whom it makes worse and in the very severe cases it seems to retard recovery. There is a small minority, however, who are always helped by it. It should never be given for more than fifteen minutes at first, or at night until it has been ascertained that it does not produce insomnia, and frequently it will prove best to defer it until the patient is taken out of bed and craves exercise.

THE BACTERIOLOGY OF TYPHOID FEVER.

By WM. H. PARK, M.D.,[1]
OF NEW YORK.

In bringing this subject before the Association I will try to confine my remarks to those points which are of practical importance to the physician. In all characteristic cases of typhoid fever the bacillus, known as the typhoid bacillus, is constantly present in enormous numbers in the tissues of the ulcerated Peyer's patches and in the adjacent mesenteric lymph-nodes. The bacilli are also, after the second week of the disease, usually present, in large numbers in the spleen and in small or moderate numbers in the blood. In pneumonia, periostitis, and abscess formation complicating typhoid fever the typhoid bacillus is frequently found in the diseased areas. The above statements refer chiefly to the characteristic cases of typhoid fever. Research has shown that it is perfectly possible to have infection with the typhoid bacillus without its localization in the intestines, and especially within the Peyer's patches. Even fatal forms occur where there are no noticeable intestinal lesions whatever. In some of these the disease is of the nature of septicemia, in others there is a localization of the process in the pelvis of a kidney, in the gall-bladder, in the periosteum of some bone or in some other tissue of the body. It is important to recognize the occurrence of these irregular cases both from a hygienic and a diagnostic standpoint. Otherwise, for instance, we would overlook cases of typhoid cystitis and allow infection of hands to occur, and we would also have a false opinion of the value of the serum (Widal) test, since we would obtain in some cases the reaction where typhoid infection was present but typical symptoms absent.

The Elimination of the Typhoid Bacillus from the Body.—The typhoid bacillus is fairly constantly present in the feces of typhoid patients. This is not because it grows in the intestinal contents, but because of its being thrown into the intestines from the ulcerated mucous membranes. It remains alive until the intestinal contents are voided. In the feces of some individuals the typhoid bacillus dies in the course of a few hours, while in those of others it remains alive for days and even weeks. In some, indeed, the bacillus actually increases in numbers. These facts explain the great variability in the numbers of typhoid bacilli found in the feces of typhoid-fever patients, and are of importance in connection with the dissemination of the disease and the bacteriological examinations of feces for diagnostic purposes. As to the value of the examinations for purposes of diagnosis the following figures and remarks have been given me by Dr. Hiss from his examination of samples sent into the laboratories of the Department of Health of New York City. Three hundred and twenty-six different cases were investigated by him in the regular diagnostic work of the Department. These 326 cases represent about 400 specimens of feces examined.

Many of these cases were positively not typhoid fever. In others the final clinical diagnosis was doubtful; in others still no diagnosis (final) was ever sent to us.

Cases here recorded as typhoid fever are those represented by a positive clinical diagnosis at the end of the disease, a positive Widal reaction, or the isolation of the specific organisms.

These cases number 121. Of these, typhoid organisms were found in the feces from 42, and were not found in 79. Of the 42 positive cases, a serum reaction was obtained in 27; was absent in the specimens examined in 3; was not tested in 12. Of the 79 negative cases, 73 gave the serum reaction, 2 failed to give it, and 4 cases were not tested. Among these cases were 10 convalescent patients, in which we would expect no organisms, and 7 in which, strange to relate, the stools had been sterilized before being sent to the laboratory.

At least one-half of the remaining cases are represented by specimens sent early in the disease. Many of the serum reactions recorded were only determined late in the disease after several examinations, while in the large majority of cases only one stool was examined, and that one, as already stated, early. Subtracting the 7 cases in which sterilized stools were received, and the 10 convalescent cases, we have 121 minus 17 or 104 cases. Of these 42 were positive (40 per cent). and 62 negative.

It must also be remembered that many of the specimens were in what seemed to us very bad condition, often having been delayed in transit several days. From the above results we are justified, I believe, in concluding that, from a diagnostic point of view, the Widal reaction will fix the diagnosis as soon as the culture examination. On account of the trouble in obtaining, sending, and examining bacteriologically specimens of feces, it is better to be satisfied with the serum-test unless, it proving negative, the case is of sufficient importance to have a search made for the typhoid bacillus. The specimen, not sterilized, should then be collected in a clean bottle, kept cool and sent quickly to the laboratory.

Typhoid Bacilli in Gall-bladder. — Suppurative cholecystitis has long been recognized as a complication of typhoid fever. It has become now of added interest as a possible source of causing ty-

[1] Read at the Sixteenth Annual Meeting of the New York State Medical Association, Held in New York, September 23-26, 1899.

phoid infection through the elimination of typhoid bacilli by the feces.

Flexner found in fifty per cent. of fatal cases of typhoid fever pure cultures of typhoid bacilli in the gall-bladder. Cultures have now been made during operations for stone from the gall-bladder of a number of cases months and years after a typhoid infection, and some extraordinary results have been met with. Thus, in cases at the Johns Hopkins Hospital, Miller obtained a culture of typhoid bacillus from a case seven years after recovery from typhoid fever; Cushing from a case where no typhoid had ever been known, and one in which an obscure history of typhoid fever twenty years before was given.

It is probable that in many of these cases the typhoid bacillus does not pass out of the body in the feces, but, on the other hand, in some cases we must believe that it does. Here, as in the case of chronic cystitis following typhoid fever, we allow persons to go about scattering infection which at any time may find conditions suitable for causing an epidemic of typhoid fever.

Typhoid Bacilli in the Urine.—Of even more importance than the consideration of the presence of the bacilli in feces, because less generally recognized, is that of their frequent occurrence in great numbers in the urine. The results of the examinations of the urine by others as well as by ourselves indicate that the typhoid bacilli are not apt to be found in the urine until the beginning of the third week of the fever, or often not until much later. From this time to the period of convalescence they appear in about twenty per cent. of the cases, and usually in pure culture and in enormous numbers. Of 9 positive hospital cases out of 38 examined by Richardson in his first series, 2 died and 7 were discharged. At the time of their discharge their urine was loaded with typhoid bacilli. We have noted many similar cases. In many convalescents the bacilli persist in the urine for weeks. Undoubtedly in some cases they persist for months and years, for Gwyn found them at Johns Hopkins in a case of chronic cystitis following an attack of typhoid which occurred four years before. Cases of cystitis following typhoid should always be suspected to be due to the typhoid bacillus, and the urine should be always disinfected. When we think of the chances such patients have to spread infection as they pass from place to place, voiding urine full of typhoid bacilli, we begin to realize how epidemics can start without apparent cause. The more we investigate the persistence of bacteria in convalescent cases of disease the more difficult the prevention of their dissemination is seen to be. The disinfection of the urine should always be looked after in typhoid fever, and convalescents should not be allowed to go to places where contamination of the water-supply is possible without at least warning them of the necessity of great care in disinfecting their urine for some weeks. Richardson made the interesting discovery that after washing out the bladder a few times with a weak solution of bichlorid of mercury, 1 to 50,000, the typhoid bacilli no longer appeared in the urine. This treatment carried out by others has frequently succeeded, but also at times has failed. Urotropin internally, 10 grains three times a day, has also given good results in some cases, but even when persisted in this may fail. The bacilli may apparently disappear for a day or two only to reappear later.

How Does Infection with the Typhoid Bacillus Occur?—Not only do the very great majority of cases examined bacteriologically and pathologically, go to show but the epidemiological history of the disease also proves that the chief mode of invasion of the typhoid bacillus is by way of the mouth and stomach. We have already considered the development of the bacillus in the body and the paths by which it is eliminated.

It is also of considerable practical importance to know the duration of life of the typhoid bacillus outside of the body. In feces it lives for a very variable time; sometimes it remains alive but a few hours, usually a few days, often for a number of weeks, and exceptionally for several months. As a rule, the bacilli can be detected in water no longer than fourteen days after introduction. Foote says that they can be found in living oysters for at least a month. The life of the typhoid bacillus varies according to the soil in which it is placed, to the abundance and varieties of the bacteria associated with it, and according to the presence or absence of such injurious influences as high temperature, light, desiccation, etc. All our information indicates that the typoid bacilli increase largely in the human body, and simply remain alive for a shorter or longer time in the feces or the urine or substances contaminated by them. Exceptionally, as when milk is infected, actual increase of the bacilli outside of the body may occur. The persistence for years in chronic cystitis and cholecystitis following typhoid fever reveals two hidden sources of infection.

The bacilli may reach the mouth by means of fingers infected with urine, or feces, or articles of various kinds, or by the ingestion of infected food, milk, water, etc., or by more obscure ways, such as the contamination of food by flies and other insects, or by the inhalation through the mouth of dust containing typhoid bacilli. Of the greatest importance, however, is the production of infection by contami-

nated drinking water or milk, one or the other of these being the explanation for the majority of epidemics of typhoid fever. In many cases indirect proof of this mode of infection has been found in the known contamination of the water with typhoid feces or urine, and in some few cases it has been confirmed by direct proof in finding the bacilli. Examples of infection from water and milk have come frequently under our direct observation. For instance, a large force of workmen obtained their drinking-water from a well very near to their work; typhoid fever broke out and continued to spread until the well was filled up. Investigation showed that some of the sick, before their discovery, repeatedly infected the soil surrounding the well with their urine and feces. Another instance of milk infection secondary to water infection was that of a milk dealer whose son came home suffering from typhoid fever. The intestinal movements were thrown into a small stream which ran into a pond in which the milk-cans were washed. A very alarming epidemic of typhoid developed, which was confined to the houses and asylums supplied with this milk. In our late war not only water infection, but food infection, was noticeable, as in the case of a regiment where certain companies were badly infected while others nearly escaped. Each company had its separate kitchen and food-supply, and much of the infection could be traced to the food.

Of more unusual origin are the too following examples of ice and shellfish contamination:

In the first epidemic the ice supply seemed to be undoubtedly the cause, as typhoid fever practically only occurred in those houses where the ice was supplied. Those using the same water and milk, but not the ice, as the people infected, were not attacked. It was found that in the winter a case of typhoid fever occurred near the pond and the stools were thrown on the ice. The epidemic occurred in August and the feces were thrown on the ice the previous January.

The epidemic at Exeter of typhoid fever certainly indicates that the eating of shell-fish is a possible cause of typhoid fever. Of eighty-five cases of typhoid fever reported in Exeter in the month of August, fifty-eight of the persons had eaten raw cockles at school picnics on July 11th and 20th at Exmouth. The cockles were taken from a mud bank over which a sewer discharged and this sewer had on its line several cases of enteric fever. Colon bacilli were found in the cockles but no typhoid. This examination was necessarily some weeks after the time that the supposed infection occurred. This and similar epidemics, although they have not been absolutely proved to have been caused by the shell-fish, teach us the need of supervision if they are to be eaten raw.

Insects as Carriers of Infection.—These are reported by Oelli to become infected with typhoid and excrete the bacilli in their feces. They certainly can transport bacilli on their feet, as we have proved by having flies alight on infected feces and then walk over culture media.

Immunization.—The injection of 5 c.c. of the serum of a well immunized horse will give at least a fair immunity for several weeks. No bad symptoms follow the injection except an occasional rash. Another means has also been employed similar to Pfeiffer's or Haffkine's preventive injections for cholera and the plague. Small amounts, grm. .002 of an agar culture of typhoid bacilli are sterilized by heat at 55° C., or by one-half per cent. carbolic acid or other suitable disinfectant and injected subcutaneously. A rise of temperature occurs in about five hours which rarely exceeds 101° F., and rarely lasts over twenty-four to thirty-six hours. With the fever may be slight chilly sensations, some nausea and dizziness. The local reaction in some cases is quite marked and local tenderness and swelling may persist for from three to five days. According to tests by Pfeiffer, Kolle, and others the protective substances in persons thus injected are as abundant and as lasting as after an attack of typhoid fever. These injections have been used in a considerable number of troops, especially in India, and appear to give quite marked protection for some months. Wright states that of 200 attendants at Maidstone Hospital 95 were inoculated. None of these contracted typhoid in the epidemic, while of the remaining 105 not inoculated 19 contracted the disease. At Khartoum, of 8 subalterns 6 were inoculated. Two decided to take their chances of contracting typhoid fever rather than try the inoculations. Both sickened and one died, not one of the six immunized was attacked. This of course was an extreme instance. Wright has inoculated over 3,000 troops with no accidents.

It would seem that for persons who expect to run great danger of infection these preventive inoculations are entirely practical and should be insisted on in armies. They are now being used in some of the troops sent from England to Africa, so that we shall soon accumulate positive information on the subject. The serum acts immediately but the immunity following lasts but a short time. The injections of the culture produce immunity only after five days, but it persists much longer. As only dead cultures are used no infection is possible.

Widal- or Serum-Reaction.—It is important that the culture employed for serum tests should be one to which we are accustomed. A culture of the typhoid

bacillus in slightly alkaline bouillon grown for not over twenty hours, in which the bacilli are isolated and actively motile, has been found to give the most satisfactory results. Stock cultures of typhoid bacilli can be developed on nutrient agar and the tubes sealed and kept in the ice-box. These remain good for months and even years. From time to time one of these is taken out and used to start a fresh series of bouillon cultures. The serum-test, is in a sense quantitative and not qualitative. By this is not meant that the agglutinating and immobilizing substances produced in the blood of a patient suffering from typhoid infection are the same as those present at times in normal blood or those produced in the blood of persons sick from other infection, but merely that the effect on the bacilli, as seen under the microscope, is identical; the difference being that in typhoid fever, as a rule, substances which cause this reaction are usually far in excess of the amount which ever appears in non-typhoid blood, so that the reaction occurs after the addition to the culture of far smaller quantities of serum than in other diseases.

The results obtained in the Health Department Laboratories, as well as elsewhere, have shown that in a certain proportion of cases, not typhoid fever, there occurs a delayed moderate reaction in a 1 to 10 or 1 to 20 dilution of serum or blood (the proportions originally proposed by Widal), but that probably never, excepting in typhoid fever, or at least typhoid infection, does a complete reaction occur in these dilutions within ten minutes. It is well to note that "typhoid fever" and "typhoid infection" are not synonymous. There may be even death from typhoid infection without intestinal lesions or the usual symptoms. When dried blood is used the slight tendency of non-typhoid blood in 1 to 10 dilution to produce agglutination is increased by the presence of the fibrinous clumps, and perhaps by other substances derived from the disintegrated blood-cells. We may sum up by saying that from many hundreds of cases examined by Fraenkel, Stern, Foster, Scholtz, ourselves and others, it has been found that in dilutions of 1 to 20 or more, a decided, quick reaction is never produced in any febrile disease other than typhoid, while in typhoid fever such a distinct reaction often occurs with dilutions of 1 to 50.

The mode of procedure, therefore, as now employed is as follows: The test is first made with the typhoid bacillus in a 10 per cent. solution of serum or blood. In the case of serum, one part is added to nine of the bouillon culture. With dried blood, a solution of the blood is first made, and the final dilution guessed from the color of the mixed culture and blood solution.[1] If there is no reaction, that is to say, if within five minutes no marked change is noted in the motility of the bacilli, and no considerable clumping occurs, nothing more is needed; the result is negative so far as this specimen is concerned. If complete clumping and immobilization of the bacilli occur almost immediately this is denominated "a marked immediate typhoid reaction," and no further test is necessary, though it is often advisable to confirm the reaction with higher dilutions up to 1 to 50. If, however, on examination of the mixture in a hanging drop there is no marked immediate reaction, but the bacilli only show an inhibition in their motility and a tendency to clump, which become more marked within ten minutes, this is called "a probable typhoid reaction." The time allowed for the development of the reaction with the higher dilutions is by many from one to two hours, but to us thirty minutes seem sufficient. Positive results obtained in this way may be taken to be conclusive unless there be grounds for suspecting that the reaction may be owing to a previous fairly recent attack. The absence of reaction in one examination in no way excludes typhoid infection. If the case remains clinically doubtful, the examination should be repeated within a week.

Proportion of Cases of Typhoid Fever in which a Definite Reaction Occurs, and the Time of its Appearance.—Of the large number of cases examined in the Health Department laboratories, 20 per cent. gave positive results in the first week; about 60 per cent. in the second week; about 80 per cent. in the third week; about 85 per cent. in the fourth week and about 75 per cent in the second month of the disease. In 90 per cent. of the cases in which repeated examinations were made (hospital cases) a definite typhoid reaction was present at some time during the illness. The majority of the cases examined which gave no reaction by the twenty-first day failed to give at any time a definite reaction; exceptionally, however, the reaction did not appear until the fourth week, or in the relapse.

Persistence of the Reaction.—This peculiar property of the blood-serum usually persists in persons who have recovered from typhoid fever for several months and occasionally to a slight extent for years. An immediate marked reaction has never been observed in a 1 to 10 dilution of the blood-serum of over one hundred healthy persons examined in the Health Department Laboratories. In several hundred cases of disease other than typhoid fever only rarely did the serum give a marked immediate reaction in a 1 to 10 dilution, and here a complica-

[1] To obtain the standard dilution colors certain amounts of fluid blood are dried and then mixed with definite amounts of water.

ting typhoid infection is probable, though several cases, which had so far as we could tell no typhoid infection, gave a delayed partial reaction.

CLINICAL LECTURE.

ULCERATIVE STOMATITIS; ANEURISM OF THE AORTA; CHRONIC NEPHRITIS: ERYSIPELAS OF THE FACE.[1]

BY H. A. HARE, M D.,
OF PHILADELPHIA;
PROFESSOR OF THERAPEUTICS IN THE JEFFERSON COLLEGE AND PHYSICIAN TO THE HOSPITAL.

THE first patient that I show you to day is a little girl eight years of age who has been brought here by her mother because of a very violent inflammation of the mucous membrane of her mouth. Owing to the straightened circumstances of her parents she has been for a number of months an inmate of one of the large homes for destitute children in this city, and while, as a rule, the care of children in these institutions is admirable, this particular child has evidently been neglected; since on the visit of her mother to her yesterday, the present condition of affairs was revealed with the result that the parents immediately removed the child from the institution.

You will notice that the expression in the child's face is that of continual pain but that she cries very little; that her lips are everted and swollen and that she keeps the muscles of her face fixed in order to avoid any movements which would increase the pain which is produced by the severe ulceration in her mouth.

An examination of the buccal mucous membrane on both sides of the teeth shows that considerable ulceration has taken place and on the right side there is a large ulcer almost as big as a quarter of a dollar, which is so broad and deep that the induration underlying it extends to the skin of the cheek so that the cheek of the child feels as if a large foreign body had been introduced into it. As a result palpation reveals a great deal of brawniness of the skin, and this makes us fear that should the ulceration persist, a perforating ulcer of the cheek may develop, and the child may suffer from what is known as noma, which is an exceedingly grave condition, rarely, if ever seen except in children suffering from profound impairment of nutrition, and which is nearly always fatal both because of the severity of the lesion itself, and because the general condition of the child is so bad that it cannot withstand the severe suppuration of the ulcerative process. You will also notice that on the margins of the tongue and that on the gums around the teeth and on the lower lip on its inner surface are to be found a number of small ulcers which are quite deep and surrounded by an indurated area; and also there is a considerable flow of saliva from the mouth, which is produced by the irritation.

We have before us, therefore, a case of severe ulcerative stomatitis which will require active interference in the way of local treatment. At the same time the greatest possible care is needed in the treatment of the child's general system.

You will meet with many cases of simple catarrhal stomatitis in practice, but unless you are connected with some institution to which many children in a depraved state of health are admitted you will rarely see such a case as this. The child, like many other children who have been forced to depend upon themselves to a large extent, is older than one would expect from a statement of her years, and I feel convinced that she is sufficiently intelligent to be able use a mouth-wash. I have therefore, given her a prescription which contains:

℞	Potassium chlorate . . .	gr. xx
	Tinct. myrrh	*m.* xxx
	Elix. of calisaya	℥ j.

This is to be diluted one-half with water, and used as a mouth-wash.

If on examination of her urine we find that it is normal and that the kidneys are not irritated, I shall direct that half a dram of this mixture shall be given to the child, internally, every six hours, since the chlorate of potassium is eliminated by the salivary glands, and will continually bathe the inflamed mucous membrane.

Some of these ulcers may also be advantageously affected by touching them with a solid stick of nitrate of silver, and the pain of this application may to a large extent be decreased by applying cocain beforehand. Care must be taken that much cocain is not employed, since if it is swallowed or absorbed it may produce disagreeable symptoms, and furthermore by dilation of the capillaries in the healthy mucous membrane may disturb the local nutrition of the mucous membrane of the mouth.

The second patient that I wish to speak to you about is a man who comes before us suffering from a very large aneurism of the descending portion of the aortic arch. It has eroded part of his ribs and sternum, and is protruding at least two inches above the level of his chest wall, yet curiously enough he has at no time suffered any pain whatever, nor is there any evidence of pressure upon nerves, blood-vessels, or bronchial tubes. He has some dyspnea on exertion, and is forced to keep to his bed because of the palpitation of the heart which ensues if he makes any effort. Because of the fact that his aneurism is typically of the sacculated form, the patient presents a type of that variety of aneurism which should be treated by means of the introduction of a coil of gold wire and electrolysis. You will remember that I performed this operation in this clinic in March, 1898, with much benefit in a case of aortic aneurism, and although the man died a number of months later from an extension of the aneurism in the distal portion of the aorta, the operation itself may be considered a distinct success because he lived for a number of months in comparative comfort, and was up and about, whereas he had been bedridden before the operation. I have performed this operation in another case which I am about to report in one of the medical journals, with an equal degree of success. One would suppose that the introduction of a large hollow needle through the thin wall of an aneurismal sac might tend to produce sudden rupture of the sac and instant death.

[1] A Medical Clinic at the Jefferson Medical College Hospital.

But the operation has been performed twenty-five times so far as I know, and in no instance has this accident taken place. During the last year I believe that the operation has been performed as frequently as it had been done in the preceding five years, largely because of the good results which have ensued.

The third case that I wish to show you is a man who is suffering from chronic parenchymatous nephritis. You will notice the pallor of his skin which is quite characteristic of the disease, and you will also notice that his face is slightly puffy and that his lower extremities are slightly edematous. In the presence of any condition of edema, it is always your duty to carefully examine the heart in order to discover whether it is in any way responsible for the effusion of fluid into the subcutaneous tissues. If it is, the patient should receive some cardiac tonic, such as digitalis, with the object of improving the action of the heart. If, on the other hand, the heart-muscle seems to be doing its work properly, digitalis is not needed, and you may, if you choose, administer a preparation which for many years has had great popularity in this condition, namely: liquor ferri et ammonii acetatis, or Basham's Mixture, which preparation is supposed, by reason of the iron which it contains, to relieve the anemia, and by reason of the acetate of ammonium to act as a diuretic and so increase urinary flow. I am convinced that in a considerable proportion of cases it is wiser to administer a small dose of iron in pill or other form, and to give the liquor ammonii acetatis alone; as, under these circumstances, the patient gets the diuretic influence without having his system overloaded with iron. There are but a very few grains of iron in a healthy person's body, and the administration of several grains a day places a quantity of this material in the body of the patient which is far in excess of its needs, and which must be stored or eliminated. Moreover, large doses of iron are somewhat apt to produce constipation and "fulness of the head;" both of which conditions are to be avoided in the presence of renal disease, since the bowels ought always to be kept active in order to aid the kidneys in eliminating all impurities from the body. In some of these cases where the kidneys seem to be exceedingly torpid very good results follow the combination of liquor ammonii acetatis and small doses of tincture of cantharides, about 1 or 2 minims of the latter at the most, three times in twenty-four hours. With this treatment the urinary flow is frequently markedly increased. Another remedy which you should remember is useful in this class of cases is the old-fashioned mixture containing bitartrate, or acetate, of potassium and juniper berries. An ounce of juniper berries is added to a pint and a half of water, and this is boiled down to a pint. The fluid is then strained, and to it is added ½ to 1 ounce of bitartrate of potassium. This mixture is then given to the patient in wineglassful-doses, so that he takes the entire quantity in twenty-four or thirty-six hours. This usually produces a profuse urinary flow, and is also apt to move the bowels.

The last case that I show you is one of erysipelas of the face. The infection has evidently taken place from a break in the skin at the angle of the nostril. This is a common point of entrance for the infectious micro-organism of erysipelas, which, you will remember, is practically identical with the streptococcus of ordinary pus. Every case of facial erysipelas which I have seen during the past ten or twelve years I have treated by first cleansing the skin thoroughly with antiseptic lotions and then applying quite a thick layer of ichthyol ointment of the strength of 2 or 3 drams to 1 ounce of lanolin. A piece of surgical lint large enough to cover the face, with holes cut in it for the nose, eyes, and mouth, after having been smeared with the ointment, is laid over the inflamed parts. This application is a very efficient one in relieving the sensation of pain and burning, and while the odor of ichthyol is somewhat objectionable to some persons, its efficiency overcomes this slight disadvantage. To a certain extent the odor of ichthyol can be overcome, you will remember, by adding to the ointment a few drops of oil of citronella.

CLINICAL MEMORANDUM.

THE TREATMENT OF THE PERITONEAL CAVITY IN CERTAIN RARE FORMS OF INFECTION FROM APPENDICITIS.

BY JOHN A. WYETH, M.D.,
OF NEW YORK;
PROFESSOR OF SURGERY AT THE NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

THE two following cases are submitted to demonstrate; first, the method of disinfection, as far as possible, of the general peritoneal surfaces of the abdominal cavity after a widespead infection due to peritonitis, and; second, the method of dealing with a partial or localised infection.

CASE I.—V. L., male, aged twenty-seven years, lawyer. Family and previous histories have no bearing on this case as presented. On the night of February 24, 1899, having eaten heartily at dinner at 7 o'clock, and added to this a heavy supper at midnight, he retired at 1 A.M., but could not sleep on account of restlessness and certain painful sensations which seemed generally diffused over the abdominal region. Early on the morning of the 25th, of his own accord, the patient took two Carter's liver pills, followed later by free draughts of Hunyadi water. This produced free purgation, but no especial relief to the pains which continued, but which were not severe enough to require the attendance of a physician until midnight of the 25th, twenty-four hours after the first symptom of his illness. His temperature at this time was 103.6° F., pulse 140. At 9 o'clock in the morning of the following day, thirty-two hours after the first suggestion of trouble, I saw the patient. His pulse was 120, temperature 103.2° F.; abdominal walls rigid and excessively tender over the region of the appendix. His face wore the expression of collapse peculiar to those suffering from dangerous lesions of the abdominal viscera or of general peritonitis. He was carefully lifted to a stretcher without leaving the recumbent position, placed in an ambulance and conveyed to the private pavilion of the New York Polyclinic Medical School and Hospital.

I operated on him at 2 o'clock, February 26th, thirty-

eight hours after the first symptoms. On opening the abdomen a quantity of seropurulent liquid flowed from the general peritoneal cavity. This fluid had the offensive odor common to general peritonitis following gangrene of the appendix, or from perforation of the intestine. The appendix was found gangrenous but was not yet ruptured. It was tied off close to the cecum and general irrigation of the entire peritoneal surfaces was done in the following manner:

A normal salt solution, at a temperature of 116° F. to 115° F., was placed in a large irrigator at a height of about five feet above the level of the patient. To the end of a pipette a good sized rubber tube was attached, and this was carried first into the upper portions of the patient's abdomen in the region of the spleen which was thoroughly flushed with the salt solution. The end of the tube was then carried in front of the transverse colon and over the stomach, underneath the omentum; then into the hepatic region, behind the pockets formed between the ascending and descending colon and the abdominal wall. The quantity forced through in this portion (the upper part of the abdominal cavity) was two to three gallons. The same general flushing was applied to the deeper portion of the cavity, the fluid being allowed to run out through the incision after it had over-distended the abdominal cavity. I then repeated this irrigation thoroughly. By the use of long streamers or pieces of sterile gauze, carried in by the hand, as much of the fluid was removed as was possible. I consider this an essential feature in the treatment of this particular form of general peritonitis, and extraordinary care should be given to the various pockets which exist behind the ascending and descending colon, and to the under surfaces of the liver, spleen, stomach, and the great omentum.

The same drying out process was applied to the loops of the small intestines and to the pelvis, to which the greatest attention should be given. A good-sized wick of absorbent gauze was then placed behind the bladder in the most dependent portion of the pelvic cavity and brought out at the external wound. Another large wicker drain was laid along the outer side of the ascending colon and also brought out at the incision. Sutures of silkworm gut were inserted but the edges of the wound were not approximated at the time of the operation, this being left open for drainage. The patient rallied well from the operation, temperature gradually declining, and recovery was uneventful. The gauze packing and drains were removed on the third day, and two rubber tubes inserted in the tracks which the gauze left. At this time the silkworm gut sutures were tied so as to bring the edges of the wound well together, but without too much pressure on the tubes. The patient was required to remain in a recumbent posture for six weeks in order to permit as complete a union of the wound as possible, and to guard against the formation of a ventral hernia. At this time, nine months having elapsed, he has no suggestion of ventral hernia and is in excellent condition.

Case II.—E. B., male, five years old. On September 19, 1899, the child complained of pains in the abdomen, vomited, and was found to have slight elevation of temperature. His father, an army surgeon, gave him purgatives, cleansing the bowels thoroughly. Symptoms of pain and the fever disappeared.

On the 22d of September the symptoms recurred, temperature was found to be 102.5° F., and pulse 100. By this time the pains were well localized over the region of the appendix. The child was brought to my private infirmary on this same date (September 22d), and on examination his condition was deplorable. Although the temperature was only 101° F., and the pulse 100, he was in marked collapse. His father told me that he had noticed symptoms of collapse while on the train coming to the city. It is very probable that the rupture of the appendix demonstrated by the operation occurred at that time.

I placed him at once under the influence of chloroform, and upon opening the abdomen found a gangrenous appendix which had ruptured. A large quantity (probably as much as two teacupfuls) of soft fecal or intestinal contents had escaped and was in contact with a very considerable surface of the peritoneum of the abdominal wall and contiguous loops of the intestines. A general peritonitis was not yet established as in the preceding case. After tying off the appendix all the loops of the intestines which were found in contact with the escaped feces were thoroughly cleansed. The child was tilted to the right side, and the intestine was thoroughly mopped with wisps of gauze dipped in 1 to 2000 bichlorid solution, and dried as soon as the washing was completed. Not more than one foot of the intestine at a time was brought out through the incision, and this was returned as soon as it was cleansed. The peritoneal surfaces, other than intestinal, were then thoroughly mopped off in the same way and dried. As there was no general peritonitis, no general flushing of the cavity was undertaken.

An effort was made to hold all portions of the intestines which had come in contact with infectious material as near the wound of incision as possible. These were walled off from the general cavity with layers of gauze, and silkworm gut sutures inserted so that the edges of the wound might later be approximated. A good-sized wicker drain was placed between the cecum and ascending colon and the abdominal wall, and a large wicker gauze drain carried down into the lowest portion of the pelvic cavity in contact with the posterior surfaces of the bladder. The child rallied from the operation, was kept carefully on the back, tilted a little towards the right side. No opiates were administered. Twenty-four hours after the operation, symptoms of obstruction of the intestines being present, which I feared were due to the packings of gauze, the child was again placed under chloroform and all the gauze carefully removed. As the distention of the intestines was not immediately relieved by this procedure, a second exploratory wound was made above the umbilicus in order to render it positive that there was no twist or knuckle obstructing the lumen of the bowels at this point. While the patient was under the anesthetic an enema of two ounces of sulphate of magnesia was thrown into the rectum and sigmoid colon.

The bowels moved within six hours after the operation and with this all symptoms of obstruction disappeared and the patient made an uneventful recovery.

The method carried out in the first of the foregoing cases is one that I always practise when there is a well-established general peritonitis with a large quantity of fluid which has the peculiar, strong, offensive odor of decomposition which is met with in the larger proportion of these cases. The irrigation is essential and the careful drying out of the cavity is in my opinion equally an important feature of the treatment. In certain cases when there is a very considerable quantity of fluid which has been brought in contact with the intestines, but which has not an offensive smell, it is the better practice in my opinion to drain the fluid and dry the peritoneal surfaces without irrigation. When the infectious material has not been walled off by adhesions, but has spread over a limited area of the free peritoneal cavity in the neighborhood of the appendix or in the deeper portions of the pelvis, it is better not to irrigate for fear of carrying the infection to those portions of the abdominal cavity not yet involved. In this case it is better, through a free incision, to practise local disinfection and establish wicker drainage from the two important points, *viz.:* the cul-de-sac between the cecum, ascending colon, and abdominal wall, and the lowest portion of the pelvis, immediately behind the bladder. In certain instances, in women, it is advisable, after disinfecting the vagina as thoroughly as possible, to open through Douglas' pouch, using gauze drainage in this direction.

The administration of calomel triturates and salines to move the bowels every day is an essential adjuvant to the management of these cases, while the employment of narcotics is contraindicated.

MEDICAL PROGRESS.

What Is the Secret of Cure of an Ulcer of the Leg?—CHIPAULT (*Centralb. für Chir.*, October 7, 1899) lays stress on the frequent change of the dressing and bandage in the treatment of ulcerations of the leg. As granulations rapidly accustom themselves to a stimulating medicinal substance, it is, therefore, necessary to change the application every few days. He attributes the success which some men have in the cure of these ulcers to the fact that in their practice they follow out these principles.

Endocarditis and Bacillus Influenza.—MABEL F. AUSTIN in a preliminary report (*Johns Hopkins Hospital Bulletin*, October, 1899) amplifies our knowledge of the relationship existing between influenza and endocarditis. The occurrence of endocarditis during an attack of influenza as a clinical fact has been known for some time, but the presence of the micro-organism, though demonstrated for other tissues of the body, has not before been reported in the endocardium. In this contribution an organism closely agreeing in its morphological features to the bacillus influenza is described as having been isolated from three fatal cases of influenza. Unfortunately the investigator was unable to cultivate the bacillus, and hence the absolute proof of casual relationship is not obtained.

Hematoma of the Neck Simulating Aneurism.—LARUE (*New Orleans Med. and Surg. Jour.*, October, 1899) describes a pulsating tumor of the neck which several physicians took to be an aneurism of the common carotid. The tumor followed a stab-wound which the patient had received by a pen-knife ten months previously, and as it had produced vertigo and an irregular heart action its removal was decided upon. When exposed it was found that it was not an aneurism, but an encapsulated hematoma, some of the clots having become laminated. The sac was opened, thoroughly cleansed, and sutured to the skin. It was interesting to note the slight change which had taken place in the blood-clots, although they had existed for nearly a year.

Methylene-blue as a Hypnotic.—VALLON and WAHL (*Le Progrès Médical*, October 21, 1899) have tested the hypnotic properties of methylene-blue by administering it to six insane patients. The result in one instance was very satisfactory. No special results followed its administration to four patients, while the delirium of one patient was rendered much worse by it, the color of the urine which he passed leading him to suppose that he had been poisoned, and giving him other ideas of persecution. After such a brief test, however, the authors hesitate to deny the claims which have been made that methylene-blue is a hypnotic in the insomnia of insanity. The medicine was given in capsules containing about 4 grains.

Fatal Case of Trichinosis.—W. T. HOWARD (*Philadelphia Med. Jour.*, December 2, 1899) gives a detailed description of a fatal case of trichinosis from both the clinical and pathological aspect. An interesting feature of the disease is the occurrence of eosinophile cells in the blood- and heart-muscles, attention to which was first called by T. K. Brown, working at Johns Hopkins. The observations of Howard confirm the findings of this worker with reference to the marked increase of eosinophile cells in the heart-muscle, but he was unable to substantiate the claim that a general eosinophilia of the blood is a constant feature. Howard believes that in acute trichinosis cells with eosinophile granulations may be stored or formed in the heart-muscle, the peribronchial tissue, and the spleen. A decided increase in the number of eosinophiles in the gastric and intestinal mucosa suggests their formation *in situ* under the influence of the trichina, while these latter were either in the intestinal canal or closely adjacent tissues.

The First Suburban Sanatorium in Russia for Indigent Tuberculous Patients.—PAVLOWSKAJA (*Rev. de la Tuberculose*, October, 1899) chronicles the inauguration of the first suburban sanatorium opened in Russia for poor phthisical patients. It is at Taitzi, and is the result of three years of agitation by a medical society at St. Petersburg. It is built upon land given by the Emperor, who also contributed half a million rubles toward its establishment. It contains accommodations for twenty men and twenty

women. In the treatment of the patients attempts have been made to realize all the advantages of good diet, abundant air, physical and moral repose, and agreeable occupation for such as are able to perform any labor. The success of the institution is shown by the fact that fifty per cent. of the patients treated during the first year were markedly improved; twenty per cent. were slightly improved, while sixteen per cent. and fourteen per cent. respectively were unimproved or died.

Cerebral Hemorrhage and Labor.—E. M. LAZARD (*Philadelphia Med. Jour.*, December 2, 1899) reports an unusual case of cerebral hemorrhage occurring during labor in a young woman of thirty-one years of age. She had had two previous confinements; one with instrumental interference, the second normal. In the present instance she gave birth to a six-month's fetus after twelve to fourteen hours of labor, and during the expulsion of the membranes became semiconscious, with accompanying stertorous breathing. Four days following labor she died. During the interval of labor and death she remained in a comatose condition, following two general convulsions, which occurred on the first day. Necropsy showed the pia mater over left occipital lobe and part of the cerebrum to be intensely congested. There was rupture of a blood-vessel in the left corpus striatum, a clot of blood extending from the posterior to the anterior part of the internal capsule, and into the lateral ventricle. There was also a small hemorrhage in the right caudate nucleus and blood on the surface of the corpus striatum.

Intestinal Obstruction Caused by a Piece of Gauze.—REHN (*Archiv für Klin. Chir.*, Bd. 60, p. 296) relates another instance to be added to the series of curious results which follow the leaving of a gauze compress in the abdominal cavity. This accident has led to fatal peritonitis, but sometimes without the occurrence of inflammation the compress has broken through into the intestine and has been passed from the anus. Rehn's patient was a woman aged thirty-two years, from whom an adherent and inflamed tube was removed by laparotomy. The pelvis was drained with gauze, which was removed on the eighth day. The wound healed in a short time, and for four months the patient was apparently well. She then complained of pains in the stomach, and a week later reentered the hospital, presenting the symptoms of intestinal obstruction. After ether was administered, a distinct tumor was palpable in the right side of the abdomen. Laparotomy was performed, and sixteen inches of the upper portion of the small intestine being found necrotic was resected. In the lumen of the resected portion of intestine was a gauze compress which, when spread out, measured about a yard square. Its presence could not be explained. The patient made a good recovery, but neither she nor the physicians were able to explain how the compress could have entered the upper portion of the small intestine.

The Influence of Marriage upon Hysterical and Chlorotic Women.—MEINERT (*Centralbl. für Gyn.*, November 4, 1899) says that formerly the idea was generally held that marriage exercised a beneficial effect upon hysteria, but that at present the opposite view is the popular one. According to his observation a change in condition is sometimes productive of benefit and sometimes the reverse is the case. In the light of the modern idea that hysteria is a psychosis, the new home of the hysterical woman after her marriage may be looked upon as a private asylum in which the hysterical patient may or may not be wisely treated. In chlorosis, too, according to this author, marriage may be productive of good or evil effects, but on totally different grounds. Here improvement keeps pace with an increase in the girth of the patient. For instance, in pregnancy, especially in the second half of it, chlorotic patients are almost invariably in an extremely good physical condition. The gradually growing uterus replaces the sunken abdominal organs and opens up the narrow aperture of the thorax, which is the cause of the chlorotic enteroptosis. This action is increased with each new pregnancy if the patient does not reproduce the previous injurious condition of affairs in the meantime by returning to tight clothing. In general the chlorotic symptoms of young women vary inversely to the circumference of their waists.

Treatment of Acute Dyspeptic Diarrhea.—KENNER (*North Carolina Med. Jour.*, November 5, 1899) treats fermentative diarrhea, which, in the vast majority of cases, is due to improper diet, by evacuation of the intestinal canal, followed by a soothing and disinfecting remedy. The best cathartic in such cases is sulphate of magnesia given in doses of ½-ounce to 1 ounce. After it has produced the characteristic watery stools, 10 grains of orphol are given every two hours. This remedy contains eighty per cent. of oxid of bismuth and twenty per cent. of betanaphtol. It will more rapidly relieve these attacks of diarrhea than any other agent which the writer has tested. A cure will, however, be fruitless unless a correct diet is also insisted on. Milk, rice, fine flour puddings and bread, toast, eggs, crackers and cheese, dried meats, and fish in small quantities should be given instead of fresh meat, fresh fish, and vegetables.

A Perfect Antidote for the Poison of Snakes and Spiders.—KENT (*Charlotte Med. Jour.*, November, 1899), has convinced himself that one of the club mosses, known as *selaginella apus*, is a perfect antidote for the poison of snakes and spiders. This plant is familiarly known as "snake-moss," and its virtues were known to the Indians of Virginia. About ½-dram of the moss is macerated thoroughly with 1 ounce of sweet milk. The milk containing small fragments of the moss is then drunk by the patient, while the balance is bound upon the wound. The writer cites a number of cases of successful use of this remedy, of which the following is a good illustration:

James T., age eleven years, was bitten over the instep of his right foot by a large copperhead moccasin. One hour after the bite he was suffering much pain, and his foot was swollen to twice its natural size. Moss was at once given with the milk, with almost immediate relief of pain. The next morning the swelling was all gone, and the boy was at play, with only the scratch of the bite to remind him of his encounter with the snake.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, DECEMBER 16, 1899.

PNEUMONIA AND ITS TREATMENT.

It is a source of gratification to be able to present to our readers this week Dr. Andrew H. Smith's able and extremely suggestive paper on this very timely subject. The interesting discussion that followed its reading at the New York Academy of Medicine also appears in another column.

Dr. Smith's views upon the essential pathology of pneumonia are certainly novel. The double circulation in the lung, the bronchial and the pulmonary, is a factor in the nosology of pneumonia deserving of serious attention, and yet, if we mistake not, this is the first instance in which it has practically been taken into consideration in its relation to pneumonia. That it must modify in an important way the course of inflammatory processes when they occur in the lung seems most reasonable. The view that pneumonia is not really a pneumonitis or true inflammation of the lung tissue, but only a growth of cultures of the pneumococcus on the serum exuded into the alveoli with consequent absorption of toxins from these cultures, to explain the constitional symptoms of the disease, may not be generally accepted in its entirety. No one can read Dr. Smith's article supporting this opinion, however, without feeling that original, suggestive, and indeed very practical theories are opened up by it.

As to the treatment of pneumonia, unfortunately it cannot be said that there is anything new. It is evident that we have yet to wait for the development of a specific, perhaps antitoxic, treatment. Authorities generally are agreed at present that the indication is for antiseptic treatment in some form. Whether the antiseptic to be employed shall be quinin or one of the salicylates or a creosote preparation is a matter of individual opinion. Very probably calomel because of its, at least, supposed antiseptic properties should be added to this list. Calomel and quinin have long been in use, however, and have largely lost their vogue. The salicylates and the creosotes are now the most popular remedies. For creosote or its carbonate there is at present a very favorable medical sentiment.

There remains as ever the symptomatic treatment. Whether ice or poultices should be used for the pain and restlessness at the beginning of the affection opinion is divided. The employment of ice is becoming more and more general in this country, however, as it has in Europe for the last ten years. Most of the remedies, quinin, the salicylates and creosotes, that are claimed to modify the course of the pneumonia itself, do undoubtedly lower the temperature. Whether it is ever advisable deliberately to lessen the fever unless hyperpyrexia, 105° F., or more, develops is an extremely doubtful question. A large series of statistics analyzed some time ago by Wilson Fox in England seems to show that the largest percentage of recovery from pneumonia occurs in cases in which the temperature during the most of the disease has ranged between 104° F. and 105° F. Fowler and Godlee, in their recent book on "Diseases of the Lungs," commenting on this, say that in their experience "a low range of temperature is not necessarily a favorable sign." They advise against all direct antipyresis when the temperature remains in the proximity of 104° F.

Sustaining treatment and stimulation still remain the sheet anchor in the treatment of pneumonia. Some years ago one of our best American clinicians said that if he were to be given on the one hand all the drugs of the pharmacopœia except alcohol, and

on the other alcohol alone, for the treatment of pneumonia, he should not hesitate to choose the latter. Despite the advances in treatment during recent years he would probably consider this view as true now as when first promulgated. Eichhorst of Zurich, a most conservative clinician, in the last edition of his text-book expresses the opinion that alcohol is not used sufficiently in pneumonia, and advises its exhibition in various forms almost from the beginning of the disease. Other stimulants are not as effective. Strychnin seems by common agreement to stand next in efficiency to alcohol. Despite Petrescu's results (two per cent. mortality in young adults) it is doubtful if the use of digitalis in large doses is advisable.

Pneumonia remains then a disease in which symptoms must be met as they arise, and in which the nursing of the patient means most. Undoubtedly at least as much harm as good has been done by supposedly specific medication. Large doses of strong drugs have been recommended at various times for the treatment of the disease even by experienced and conservative physicians, but the conviction has grown that they are a serious mistake. Drugs that are depressent in action must be used only with the greatest circumspection, no matter how cardinal the indication for which they are exhibited. The care of a pneumonia patient belongs as yet to the art not the science of medicine, and gives occasion for the exercise of the highest practical medical skill.

RECURRENCE AFTER OPERATION FOR MAMMARY CANCER.

TWENTY years ago Professor Volkmann of Halle offered the suggestion that mammary cancer removed by operation might be considered as definitely cured if there was no recurrence at the expiration of three years. The suggestion was accepted by surgeons generally as a practical working conclusion. Those were days, however, when what is recognized as radical operations for cancer of the breast were as yet unknown, and the patients that remained free from the disease at the end of three years were few. In the case of the survivors there grew up finally the suspicion that the growth could not have been malignant. Even surgeons of wide experience began to doubt if they had ever seen a case of cancer absolutely cured by operation.

As operative intervention has come to be applied earlier and earlier in the disease and the operation has become more radical, it develops that Volkmann's rule suffers many exceptions. Cases of recurrence of cancer after four years are frequently reported and not infrequently even after longer periods. Out of 90 cases operated on by Barker at University College, London, during the last twenty years, 25 are now alive, but in only 6 of the cases has more than five years elapsed since the operation. In five cases deaths from recurrence have taken place later than five years after the operation. One of the patients in whom recurrence was the cause of death had lived seven years and eight months, while two died from the same cause six years and four months after the operation. It is evident then that even the six patients who have survived the operation more than five years, without recurrence, are not thereby assured of freedom from all further cancerous invasion.

Only two patients have survived ten years since the operation, and one of these compels a most unfavorable prognosis. She has noticed a small lump for three years, the nipple has been retracted for six months, the skin is involved, the axillary glands palpably affected, and the tumor fixed to the pectoral muscle. The other patient, who is alive eleven years and seven months after operation, is in an almost equally unfavorable condition. She had noticed the tumor for five years previous to operation, and the glands in the axilla though palpable, were found at the operation extensively cancerous, though there was not in her case any adherence of the tumor to the pectoral muscle. In both cases the cancer was of the scirrhus variety, in women aged respectively forty-five and fifty-four, so that it is evident that the type of cancer is one of the most important elements in prognosis and that it means much more than either the duration of the growth or its extent, though these are usually considered the all-significant factors.

Two views of this fact of late recurrence of cancer have been recently discussed. The Italian and French students of malignant neoplasms, who consider them as due to parasites, argue that late recurrences substantiate the parasitic theory, since it is easier to understand long latency on the part of par-

asites than of tissue elements aroused to malignant action. Simpson, of University Hospital, discussing these cases of Barker's in the Liston Prize Medal Essay for 1898–1899 of University College, London (London *Lancet*, July 8, 1899), takes the position that these cases of late recurrence seem to indicate that cancer is a general infection with a special manifestation. Either of these views are of extreme interest because of their practical bearing on the cancer problem, and make clear that the careful observation and collation of cases surviving for years after successful operation may throw great light on the disease.

THE MEDICAL ARRANGEMENTS FOR THE TRANSVAAL CAMPAIGN.

The Medical Department of the British Army has adapted its organization most carefully to the needs of the campaign and the nature of the country, and so far it is working with admirable smoothness. Each army corps has roughly speaking about forty-five surgeons in immediate charge of the men at the front, who are also responsible for the sanitation of their respective camps. Under these are a full force of special Army Medical Corps men, and a supplementary body of bearer companies, one to each brigade, each one consisting of forty-four privates, three commissioned and thirteen non-commissioned officers. Thus the medical officer is not left to the pleasure of the commanding officer of the company or division for a special or chance detail of men for this important service, as was unfortunately the case on several occasions in our late experience in Cuba. About a third of these bearers accompany the regiment into action as "stretcher squads" collecting the wounded and bringing them back to the first or "collecting" station. Here will be placed the ambulances of the "first line," which will receive the men and carry them back to the dressing-station where sufficient security and leisure is afforded for a full and careful examination of the wounds. After these have been attended to and dressed the patients will be placed in the ambulance in waiting, known as the "second line," and carried back to the field hospital.

A field hospital is attached to each brigade and has equipment for 100 beds, though these are so arranged that sections of twenty-five can be utilized separately if required. Fifteen of these are already equipped and their staff consists of four medical officers and a quartermaster, twelve sergeants and corporals, twenty-three privates of the Royal Army Medical Corps, and nineteen privates of the Army Service Corps, for transport duties. From the field hospital the wounded will be sent to the nearest post provided on the railway, and those unable to travel detained at a special stationary hospital arranged at the nearest convenient point on the line, which again has accommodation for 100 patients, and an equipment similar to that of the field hospital. Four of these have already been put in the field in South Africa.

Those of the wounded who are in condition to travel will be sent on by special hospital-train or ambulance-train, of which two are already in the field, and one other in process of construction at Birmingham, to the Base Hospital, which will be at or near one of the ports of embarkation and have a capacity of 500 beds. From this point the patients will be brought by the hospital ships, "Trojan" and "Spartan" to Capetown to the Wynberg Sanatorium Hospital, and from here such as require to be invalided home will be conveyed by the new "Princess of Wales" hospital ship and the American Ladies' hospital ship "Maine" to England.

Thus a perfect chain of carefully arranged relay stations, with gradual sifting out and classifying of the cases has been planned, which on paper at least appears to leave little to be desired. As the country though which the lines of communication run is fairly well settled and fertile there ought to be little or no difficulty in getting abundance of supplies of vegetables and fresh foods at the various stations. The point regarded as likely to be weakest in the system is that of the Base Hospital in Durban, for while the climate of the high veldt, though almost tropical by day and very cold by night, is far from ideal, yet upon the whole it is regarded as healthful and rather bracing than otherwise; at the coast, on the contrary, especially during the summer season which is just beginning, the climate is hot, damp and depressing, and it would be highly desirable to either detain the wounded at some point in the interior, as long as proper supplies can be secured, or to make the stay at Durban

before transferring to the sick-transport for Capetown as short as possible.

So far everything has worked perfectly but of course as yet only about a fourth of the total strength has been actually engaged, and it remains to be seen how the system will bear the strain of the heavier casualty lists of the entire triple line of advance. One condition has been found much more favorable than was anticipated and that is, the remarkable cleanness and freedom from complications, already alluded to, of the wounds made by the Mauser bullets, so that even out of the large lists of wounded, bearing eloquent testimony to the accuracy of the Boer marksmen, which have resulted from the comparatively small engagements already fought, only a small per cent. have had to be sent further back than the field hospitals, so that the stationary hospitals are not at all crowded and no accumulation of any importance has as yet occurred at Durban.

The entire strength of this admirable army of peace which nineteenth century civilization and humanitarianism are sending into the field, to do its best to counteract the effects of the huge engine of destruction which it accompanies, amounts to nearly 3100 men and nurses with 282 medical officers of the Army Corps, and 68 civilian surgeons, almost a brigade in itself. While three hundred years ago our warlike ancestors would probably have regarded this splendid corps, as so much good material withdrawn from the fighting strength, yet as a matter of actual increase in practical fighting power there is no possible capacity in which these men could be employed to better effect. Sickness disables three times the number that either the bullet or the bayonet does, and the army which can put the largest percentage of sound and healthy men into the fighting line at the end of their advance or retreat as the case may be, is the one which is almost certain to be successful in the campaign. It is easy enough to pour men into the field in thousands, but to get them to the front in fit physical condition is a far more difficult problem, and this an efficient Army Medical Corps only can solve.

ECHOES AND NEWS.

Dr. Carr Assumes the Editorship of "Archives of Pediatrics." —With the January, 1900, number Dr. Walter Lester Carr of New York will become the editor of *Archives of Pediatrics.*

Leprosy in the Island of Guam.—In a report to the Navy Department, Lieutenant Commander V. L. Cattman, who has visited the Island of Guam, refers to the existence of leprosy in that island.

Six Children at a Birth. — It is reported that Mrs. J. Karl of Mobile, Alabama, gave birth to six male children, December, 8, 1899. Mother and children are reported as doing well.

American Nurses Honored in London.—The British Medical Society recently gave a reception to the American nurses who are to accompany the hospital ship "Maine," when she sails for South Africa.

A Practising Physician at Ninety-Six.—Dr. Charles F. H. Willgohs, the oldest physician in Ohio, has lately celebrated his ninety-sixth birthday. He is said to be in good health and to be still in active practice.

New Serum for Tuberculosis.— Dr. A. R. Jenkins of Chicago, who has studied with Professor Koch, declares he has discovered a serum which will reveal the presence of tuberculosis before it can be detected by other known means.

Medical Advisers of the Czar.—Through the *Medical Press* we learn that the Czar has no fewer than twenty-seven medical attendants. They include a physician-in-chief, honorary physician, three surgeons, and four honorary surgeons, two court physicians and three specialists for the Czarina.

Queen's Gift to the "Maine."—The Queen has given a union jack to the hospital ship "Maine" as an evidence of her gratification at the work of the American women who raised the funds for fitting out that vessel. On December 16th the Duke of Connaught presented the flag on behalf of her majesty.

An International Congress on Tuberculosis.—The *British Medical Journal* says that it is proposed to hold an international congress in London during May, 1901. The congress is to be held under the auspices of the National Association of Great Britain for the prevention of consumption and other forms of tuberculosis.

Practitioner's Society of Dallas (Texas).—On December 1st the above-named society was organized at the Hermitage Hospital and the following officers elected: Lawrence Ashton, M.D., president; J. B. Titterington, M.D., vice-president; C. L. Johnson, M.D., secretary. The next meeting will be held at the residence of the president on Monday, December 18, 1899.

Expectoration Fine Reduced. — The Health Board of Hoboken, N. J., recently reduced the fine imposed for expectorating in public places from $10 and $25 to a uniform fine of $3. It was thought that the police refrained from making arrests for the offense of expectoration be-

cause the public considered the penalty too severe. This seems to be a wise and practical movement.

A Prize Fund for Institute of France.—M. Osiris, a wealthy Parisian, noted for his charities and public spirit, has presented to the Institute of France a sum representing an annual income of 32,000 francs for a triennial prize of 100,000 francs for the most remarkable work or discovery of general interest, especially in the fields of surgery and medicine in exhibition years. The prize is open to all countries.

Business Committee of the New York State Medical Society—The President of the Medical Society of the State of New York has appointed the following Business Committee: Dr. Wendell C. Phillips, Chairman, 350 Madison Avenue, New York; Drs. Henry L. Elsner, Syracuse; Chauncy P. Biggs, Ithaca. Communications concerning papers to be presented at the next annual meeting, January 30 to February 1, 1900, should be sent to them.

Southern Medical and Gynecological Association.—The following officers were elected: President, Dr. A. M. Cartledge, Louisville, Ky. Vice-presidents, Drs. Manning Simons, Charleston, S. C., and W. P. Nicholson, Atlanta, Ga. Secretary, Dr. W. G. B. Davis of Birmingham, Ala; Treasurer, Dr. W. D. Haggard, Jr., Nashville, Tenn. Atlanta, Ga., was selected as the place for holding the next meeting in 1900. Time, second Tuesday in November.

Medical Hero of Transvaal War.—Surgeon-Captain R. A. Buntine has recently performed a valient deed under Boer fire and is likely to receive the V. C. from the authorities. While on patrol duty the Natal Carabiniers were surprised by ambushed Boers and forced to retire, leaving a wounded trooper on the ground. Dr. Buntine with his servant rode back, dismounted, placed the wounded man on his horse, and then in the midst of a sharp rifle practice, ran back to camp. All three arrived in safety.

Poisoning by Refrigerated Meat.—The poisoning of 200 soldiers from eating refrigerated meat is reported. According to a letter received 200 of the 1300 men of the Twenty-fifth Regiment were poisoned while en route to Manila on the transports "Rio de Janeiro" and "Sikh," by eating fresh beef supplied the vessels at Honolulu. One man died despite the efforts of the surgeons. A lieutenant in the regiment attributes the poisoning to a faulty refrigerating plant whereby some of the acids used in making ice came in contact with the meat.

New Jersey Sanitary Association.—The New Jersey Sanitary Association in session at Atlantic City during the past week elected officers as follows: President, George W. Howell of Morristown; first vice-president, Herbert B. Baldwin of Newark; second vice-president, H. Brewster Wills of New Burnswick; third vice-president, Dr. J. L. Leal of Paterson; recording secretary, James A. Exton of Arlington; corresponding secretary, N. L. Wilson of Elizabeth; treasurer, George H. Ollcott of East Orange; Chairman of Council, M. N. Baker of Montclair.

Agitating Mrs. Maybrick's Release from an English Prison.—In view of the fact that American women have been appealed to by Lady Randolph Churchill to assist in raising funds for the equipment of the hospital ship "Maine," the Woman's Committee of the New York Medico-Legal Society has addressed a letter to Lady Churchill asking her to seize upon the present good will and friendly obligations to urge upon the Home Secretary of England the release of Mrs. Maybrick. This American woman, it will be remembered, is now undergoing a prolonged imprisonment for the alleged murder of her husband.

Spain Left Off the Map.— It seems evident that the plague scare has upset the geographical equilibrium of our estimable contemporary the *New York Medical Journal*. In an editorial of the issue of the 18th of November, referring to a hygienic crusade against various insect-pests, they make the following interesting comment on the local geography of France and Portugal: "If the appearance of the plague on the frontier between France and Portugal leads to the destruction," etc. It may be that Spain has been lost from the map in the estimation of the editor, since our recent Cuban episode.

Contributions to the Hospital Ship "Maine."—Money continues to pour in in the most gratifying manner for the American Ladies' Hospital Ship the "Maine." One generous friend of the enterprise who refused to allow his name to be made public gave $25 000 in a single donation this week, and has promised another subscription of the same amount if the committee ultimately find it to be necessary. For some reason the Irish Transvaal Committee for the equally creditable purpose of providing an ambulance for the Boer wounded does not seem to be meeting with the same success, as its list of contributions reaches so far the easily invested total of $300.

Professor Virchow's Jubilee.—The fiftieth anniversary of Virchow's labors as Professor Ordinarius in the University of Berlin was celebrated in the hall of the Pathological Museum, which was constructed through his efforts. There was no banquet or similiar social function but the Senate of the University presented to the revered and honored professor an illuminated and illustrated address, the text of which was written by Professor Waldeyer. Virchow's wonderful achievements as scientist, archeologist, and politician were recounted therein in flattering terms. Professor Virchow is now in his seventy-eighth year, and, in spite of fatigues of the celebration, participated during the evening in a learned discussion on organotherapy.

Dr. Kendrick Really Dead—Dr. William H. Kendrick, a personal friend of Abraham Lincoln, was buried in Crown Hill Cemetery near Indianapolis on December 1st, after his family had made a careful examination to prove

that he was dead. Once before his body was prepared for burial but he revived. He was called to Washington in the Civil War at the request of President Lincoln and took a place in the army medical staff. He was stricken with pneumonia while in Washington, and after a brief illness was pronounced dead. The body was shrouded and was about to be shipped to his home when he suddenly returned to life. Dr. Kendrick was an eclectic physician and was formerly connected with the Chicago Eclectic Medical College.

Decrease in the Mortality from Consumption.—In the report for 1898 of the Massachusetts Board of Health a steady and uniform decrease in the mortality from consumption in that State is pointed out. In 1853 the deaths from it were 4272 per million people. In 1895 the number was only 2194, and the report for 1898 shows further decrease. The causes of this remarkable change, states the report, are of a similar character with those which have affected nearly the entire class of infectious or preventable diseases—namely, a better knowledge of the art of prolonging life, a growing appreciation of the value of sanitary measures, and the more rigorous enforcement of those measures which are essential to success in the campaign against infectious diseases. Another means which has recently been adopted in Massachusetts is the establishment of a special State hospital for the isolation and treatment of persons afflicted with tuberculosis.

More Medical Officers in the United States Army. — Surgeon-General Sternberg has prepared a bill for presentation to Congress providing for an increase of men in the Medical Department of the Army. This increase is necessitated by the expansion in the military organization. The bill provides for an addition to the present corps of four assistant surgeon-generals with the rank of colonel; ten deputy surgeon-generals with the rank of lieutenant-colonel; thirty surgeons with the rank of major; and eighty assistant-surgeons with the rank of lieutenant, who will have the rank of captain at the expiration of five-years' service. These positions are to be filled by seniority promotion in accordance with the established laws and regulations. Acting assistant-surgeons to the number authorized are to be appointed subject to the usual examination for a probationary period of six months, during which they will attend the Army Medical School in Washington. At the end of this time if their standing is satisfactory they will be commissioned to fill existing vacancies.

An Energetic University.—Johns Hopkins of Baltimore has demonstrated recently that not only in science but also in the every-day emergencies of life that its professors are ready, even to the exigencies of fighting fire. On the 4th of this month a fire was discovered in the chemical laboratory of the university. The fire was just beneath the private office of Professor Morse on the third floor. It spread quickly and a series of small explosions in different parts of the building made the firemen a little timid about venturing into unknown quarters. Dr. Gilpin, an associate in the chemical department, proved of great assistance to the chief in locating the really dangerous places and reassuring the men about the others. Just as President Gilman arrived upon the scene there were cries of warning as to the danger to be apprehended from the sodium in the laboratory. The disquieting explosive was ultimately removed by the colored janitor, who braved flames and danger and staggered out with the bottles in his arms. When Professor Ira Remsen arrived he was provided with a fireman's outfit—rubber coat, helmet, boots and all—and, with Chief McAfee, made a survey of the building. Dr. Harmon Morse followed Dr. Remsen to the scene, and was likewise fitted out by the chief. Both were of much assistance to the firemen.

Competition for the Senn Medal.—At the meeting of the Surgical Section of the American Medical Association, held June 4, 1897, Dr. Nicholas Senn offered to donate annually a gold medal of the value of $100 for the purpose of stimulating surgical research. The offer was accepted. The committee for this year, consisting of Drs. W. L. Rodman of Philadelphia, A. J. Ochsner of Chicago, and H. Horace Grant of Louisville, desire to direct attention to the following conditions governing the competition: (1) A gold medal of suitable design is to be conferred upon the member of the American Medical Association who shall present the best essay upon some surgical subject. (2) This medal will be known as the Nicholas Senn Prize Medal. (3) The award shall be made under the following conditions: All successful essays become the property of the association. The medal shall be conferred and honorable mention made of the two other essays considered worthy of this distinction at a general meeting of the association. The competition is to be confined to those who at the time of entering the competition, as well as at the time of conferring the medal shall be members of the American Medical Association. The competition for the medal will be closed three months before the next annual meeting of the American Medical Association, and no essays will be received after March 1, 1900. All communications should be addressed to Dr. W. L. Rodman, Chairman, 1626 Spruce street, Philadelphia.

MEDICAL MATTERS IN NEW YORK.

THE SUICIDE OF DR. LOCKWOOD — THE DEATH OF DR. STEWART B. CARLISLE — REMARKABLE CASE OF BROKEN NECK — STATIC ELECTRICITY AS A REMEDY FOR TUBERCULOSIS—FOUR DEATHS FROM ILLUMINATING GAS—CRITICISMS BY THE CORONER'S OFFICE—ANNIVERSARY OF THE PRESBYTERIAN HOSPITAL — THE NEW YORK EXCHANGE FOR WOMEN'S WORK—AN ODD CAUSE OF DEATH—FOR CHARITY CONSOLIDATION—THE NEW YORK ASSOCIATION FOR IMPROVING THE CONDITION OF THE POOR—THE RECENT BICYCLE RACE.

DR. WILLIAM A. LOCKWOOD committed suicide recently at his lodgings in the borough of Brooklyn by swallowing carbolic acid. Dr. Lockwood was born in Norwalk, Conn., and was a member of the well-known family of that name whose ancestry dates back to the founding of that city. He was at one time a leading

physician of his native town. He served for a time upon the visiting staff at Bellevue Hospital, resigning for the purpose of visiting Paris to study in the hospitals there.

Dr. Stewart B. Carlisle, living at Mt. Vernon, died in the Harlem Hospital December 8th of heart disease. Dr. Carlisle was found upon the street in an unconscious condition by a policeman, and was removed to the hospital. Dr. Carlisle was a graduate of Bellevue Medical School, Class of 1881; he was member of the Westchester County Society, and was attending physician to the Mt. Vernon Hospital.

A man dragged himself into St. Joseph's Hospital, Yonkers, recently, and asked to be admitted. He gave the history that he was sixty-five years of age, and had fallen from a scaffold five weeks before and had broken his neck. Directly after the accident he was taken to his boarding-house where a physician put his neck and head into a plaster cast. He was unconscious for two weeks and on recovering, perceiving that he suffered no pain, he dismissed the doctor. Upon examination it was discovered that the patient's left leg was paralyzed but hypersensitive to touch, while the right side was without feeling but retained the power of locomotion. The X-ray examination disclosed a fracture of the vertebra with displacement, one fragment pressing upon the spinal cord.

The medical staff of St. Luke's Hospital are watching with scientific interest a series of experiments in the application of static electricity in the treatment of phthisis. It has been the plan of the physicians not to allow any knowledge of these experiments to reach the outside world until they were able to report definite results. The experiments are being conducted by Professor Francisque Crotte, and the medical staff are acting as a jury. Careful temperature records are being kept and the sputum of the patients is being examined at stated intervals at the laboratory of the New York Board of Health. The method of applying electricity is by passing sparks through sponges saturated with formic aldehyde which are applied to the patient's chest.

Two more cases of accidental death due to failure to turn off the gas have recently occurred in New York; two people were involved in each instance, making in all four deaths.

Criticism of this city's physicians by medical representatives of the Coroner's office are "rather rife just now." The latest is that of Coroner's Physician O'Hanlon to the effect that the injuries of a patient at the Presbyterian Hospital had been diagnosed simply as fractured collar-bone. Dr. O'Hanlon found on autopsy that in addition to that injury a number of ribs had been broken, and he "expressed great indignation over the failure of the hospital physicians to discover the man's worst injuries." As a matter of fact the physicians at the Presbyterian Hospital had made themselves thoroughly acquainted with all the patient's injuries.

The thirty-fifth anniversary of the founding of the Presbyterian Hospital was celebrated December 9th with exercises in the dispensary of the institution. According to custom on the celebration of anniversaries the entire hospital was thrown open to the inspection of visitors. After a musical programme by the choir of the Central Church, Dr. Donald Sage Mackey made a short address, in which he referred to the part hospitals had taken in the advance of medicine. Fully two hundred visitors inspected the various wards, operating rooms, and laboratories.

The New York Exchange for Women's Work calls attention to its Domestic Department which will furnish all kinds of home-made delicacies for the sick at short notice. The Exchange is a charitable institution designed to help educated women in reduced circumstances, and is supported by voluntary contributions. Orders for invalids sent here are not only well filled, but the physicians who patronize the exchange will be assisting one of our most worthy charities. The Exchange is at 334 Madison avenue, corner of Forty-third street. The telephone number is 1226 Thirty-eighth street.

Mrs. Katherine Keifer died in St. Peter's Hospital in Brooklyn on December 1st after a two-weeks illness, during which her physicians were greatly puzzled. On autopsy a short piece of fine wire was found to have punctured one of her lungs. Just before her illness Mrs. Keifer swallowed a large piece of bread accidentally, and suffered great pain in doing so. The X-rays had been used, but without result.

Leading charity experts of this city are conferring for the purpose of ascertaining whether a large number of charities cannot be consolidated. It has been found that much money has been wasted owing to the duplication of such work. The chief complaints have come from the medical charities, especially the dispensaries, which have been freely criticised of late years as being little better than pauperizers. Theodore Sutro, Esq., President of the Medical and Legal Relief Society, is working for consolidation.

The fifty-sixth annual report of the New York Association for Improving the Condition of the Poor has just been issued. The Department of Relief expended $27,000 in relieving 28,020 people. The necessity of new homes for the aged and of hospitals and homes for consumptives is stated. The fresh air work of the association was exceptionally successful last summer. Fifteen thousand three hundred and seventeen people were taken on the day excursions, of which there were five each week. One thousand four hundred and ninety women, children, and babies were kept at Sea Breeze, the association's summer home on Coney Island, for an average stay of ten days each. One hundred and twenty thousand, three hundred and forty-seven baths were given at No. 9 Center Market Place. The success of these baths demonstrates the possibility of inculcating habits of cleanliness in the most densely populated parts of the city.

Many of the objectionable features that have characterized the previous six-day bicycle races were successfully eliminated from the recent contest at the Madison Square Garden. The improvement was due to the enforcement of the regulation that no contestant was allowed on the track for more than twelve hours out of twenty-four. The result has been a much more satisfactory and exciting

contest than before and popular interest was kept at the highest pitch by the closeness of the score. The sport itself has been in reality benefited by the very humane modification introduced. The management must realize that what makes for humaner methods will always increase popularity in the end. There is one more suggestion that might be adopted with advantage. It is that the untrained, or those in poor condition, should not be allowed to enter such contests. At the beginning of the recent race some unfortunate things occurred seemingly from a neglect of this precaution, and erratic mental symptoms were manifest in more than one of the contestants. The problem of providing properly for such exclusion is perhaps a difficult one, but it is a task well worth the managers' careful attention, not alone from the higher motives of humanity but even from the more sordid reasons of added popularity for the sport and consequently increased monetary returns.

MEDICAL MATTERS IN PHILADELPHIA.

[From Our Special Correspondent.]

THE TROPICAL DISEASES OF THE PHILIPPINE ISLANDS—A $2,000,000 HOME FOR CRIPPLED CHILDREN—THE THOMAS HOGE MEMORIAL WARD OF THE PRESBYTERIAN HOSPITAL—DEATH FROM FREE SAMPLES OF A PATENT MEDICINE—HEALTH REPORT FOR THE CURRENT WEEK.

PHILADELPHIA, December 9, 1899.

AT the last meeting of the College of Physicians of Philadelphia, held December 6th. Dr. Simon Flexner gave an interesting talk on "The Medical Aspect in the Philippine Islands," detailing his impressions gained last summer in the Philippines, whence he was sent, as a representative of the Johns Hopkins Hospital, to investigate certain phases of tropical diseases. Arriving in Manila in May, 1899, Dr. Flexner was enabled, through the permission of the Government and through the courtesies of the army medical officers, to very satisfactorily pursue the study of various tropical affections in patients in the various military and civil hospitals of that city. Leprosy, beri-beri, tuberculosis, and amebic dysentery were found to be the most prevalent diseases Leprosy was studied in the local leper hospital, containing about one hundred beds, and also among the Filipino prisoners at Cavite. The latter were confined in two enormous corridors, which were unlighted and unventilated, and provided adequate accommodations for not more than 100 persons, while, as a matter of fact, no less than 1200 were here confined. Two hundred cases of beri-beri developed within a few days, with a consequent mortality of about 40 per cent., the several types of this disease, the edematous, the atrophic, and the general, being observed. Clinically, no undescribed manifestations were noted; and although particular efforts were made to determine the specific cause of the disease, by approved pathologic methods, nothing definite along this line of research was accomplished, except the proof that beri-beri is not due to infection with any specific form of streptococcus. Cases in which the micro-organisms were found were undoubtedly secondarily affected. Tuberculosis is very common among the natives, and also various cutaneous diseases, scabies in particular; it is known as "washer woman's itch," and is transmitted through the medium of undergarments which have not been boiled in the laundry.

In the study of Americans suffering from various diseases the Spanish hospital, the capacity of which was increased so that 1200 patients could be accommodated, and also three reserve hospitals, chiefly for convalescents, were visited in quest of clinical material. There was found to be far less malarial fever than newspaper accounts would lead one to suppose, although instances of all types of this disease were observed. Enteric fever was also far less extensive than is popularly imagined. Dysentery was by far the most serious disorder which prevailed in the islands, some cases proving fatal in from 24 to 48 hours, while others, chronic and destructive to the patient's health and strength, dragged along a course lasting for many weeks. The complication of hepatic abscess was common. Post-mortem examinations in many cases showed that severe intestinal lesions were commonly caused by the infection, in extreme instances the mucous membranes of the large, and part of the small intestine being apparently almost wholly destroyed, and utterly unlike the bowel structure. The diphtheritic form was not common, but the amebic form was. The ameba coli were found in many cases of dysentery, as well as in individuals who did not have this disease, so that, from this fact, it is evident that the significance of the ameba as the specific cause was partially lost. By means of a careful bacteriologic study of a number of cases, Dr. Flexner believed that he could isolate a single organism, cultivated on blood-serum, as pathogenic for the disease, and to this organism was attributed a more important etiologic significance than the ameba. The organism in question resembled the typhoid bacillus rather than the colon bacillus, but differed from both, the exact points of dissimilarity being at the present time the subject of more extended laboratory investigation. It was further stated that the lesions of the intestine, and the liver complications produced by this organism were identical or very similar to those caused by ameba infection.

At the same meeting Dr. Louis F. Atlee, late surgeon of the "Olympia," gave an interesting account of his experiences with the several diseases most commonly seen in the Philippines. Tuberculosis, leprosy, beri-beri, smallpox, erysipelas, cutaneous disorders, and an anomalous form of the continued fever, came under his observation with particular frequency, and were discussed from various standpoints. The climatic conditions of the islands were thought to be particularly enervating, both to the ill and to the normal individual. The climate was responsible for much of the mental inactivity and incapacity for physical exertion, both of the natives and of the newcomers. Its effect upon European women was regarded as especially deleterious, as shown by disturbances of menstruation, by the frequency of miscarriages, and by the large percentages of births of poorly nourished children among this class of the population.

P. A. B. Widener, the tramway magnate, has signi-

fied his intention of erecting and endowing the hospital and home for crippled children in this city, at an estimated total cost of $2,000,000. The proposed institution, to be known as the Widener Industrial Home for Crippled Children, will have for its objects not only the medical and surgical care of its inmates, but also their training in common-school branches of learning, and in such industrial trades which will enable them to become partially or wholly self-supporting. Ground within the city limits has already been purchased, and the erection of the buildings of the institution will be begun as soon as the existing legal formalities are removed by Councils, making it possible to permanently improve the tract of land chosen by the donor.

The Thomas Hoge Memorial Ward of the Presbyterian Hospital was formally opened on the afternoon of December 9th, the principal speakers on this occasion being the President of the Hospital, the Rev. Dr. Chas. A. Dickey, and Dr. S. Weir Mitchell, to whom the direction of the new ward has been entrusted. This addition to the Presbyterian Hospital's already extensive collection of buildings is expressly intended for the treatment of nervous diseases, especially among that large class of the community, the "half poor," for whom special accommodations are provided, enabling them to receive the rest cure, and other elaborate and ordinarily costly modes of treatment, at an expense to the patients, commensurate with their means. The ward is unendowed so that its future patients are expected to pay a moderate sum for treatment.

The coroner is at present investigating the cause of a death of a twelve-year-old girl, who is reported to have succumbed last week to the effects of having eaten a number of patent pills, samples of which have been recently strewn about the city as an advertisement of the nostrum. If the results of the investigation justify present suspicions, the enterprising manufacturers of these deadly sugar-coated pellets will be prosecuted, and a halt called on this promiscuous distribution of quack medicines, which lately has become so prevalent a nuisance here.

During the week ending December 9th, the number of deaths reported in this city was 412, being an increase of 2 over those of last week, and a decrease of 24 compared to the number reported in the corresponding week of 1898. The following report of contagious disease was made: Diphtheria, 157 new cases, 23 deaths; enteric fever, 43 new cases, 8 deaths; and scarlet fever, 55 new cases, 3 deaths.

Salicylic Acid Administered through the Skin.—If mixed with an oily vehicle it is quickly absorbed. It may be prescribed thus in connection with its internal administration for rheumatism. Oil of wintergreen may be used instead with advantage.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

THE SURRENDER OF LEICESTER—NO NEWS, GOOD NEWS FROM SOUTH AFRICA—SUCCESS OF CONCERT IN AID OF AMERICAN HOSPITAL SHIP—SMALL-POX SPREADING AT HULL—SULPHUR AND BLUE VITRIOL AS FOOD — COSMETICS — ACROMEGALIC GIANT AT POLYCLINIC—REPORT OF COUNCIL OF ROYAL COLLEGE OF SURGEONS BY ANNUAL MEETING—MEDICAL SUPPLIES FOR TRANSVAAL FROM FRENCH, GERMAN, AND ITALIAN RED-CROSS SOCIETIES — QUACKS BROUGHT TO JUSTICE—MEDICAL MAYORS — HALF AS MANY CHILDREN AS YEARS OF AGE.

LONDON, December 2, 1899.

CIVILIZATION has triumphed in Leicester. As predicted in our last letter, the Board of Guardians, after posing as Ajax defying the thunderbolts, for nearly five months, has surrendered, and by a vote of 29 to 9 rescinded its resolution not to appoint a vaccination officer. It was a remarkable tribute to the power of chivalry even among the Philistines, for as long as the Joan of Arc of the Board stood firm the rebellious majority hung together, but when Miss Ellis weakened the rank and file were only too glad to follow her. The appointment of an officer was then agreed to by a vote of 27 to 19.

The medical news from the front this week seems to have shared in the general slackness and inactivity of all the operations during the lull before the forward movement. The former reports of the extraordinarily low mortality and freedom from complications of the wounds made by the Mauser bullets still continue to be confirmed in a most gratifying manner. One man is actually reported to have been shot completely through the head, the ball entering at one temple and going out at the other, and yet to be convalescing, and the proportion of the wounded who have died within the past four weeks stands at the very low figure of less than four per cent. The troops continue remarkably free from either typhoid or dysentery, and nearly all private correspondents describe the situation practically in the graphic phrase of an officer writing home to his sister, "The climate and surroundings are beastly but healthy."

The concert at Claridge's Hotel this week on behalf of the American Ladies' Hospital-ship was a brilliant success. Half the social lions of the hour, from the Prince of Wales to Miss Edna May, were present, and the net proceeds were something like $8000, which brings the fund to within a few thousand dollars of the amount estimated as required. Much sympathy is of course being expressed with the distressing position of the president of the association, Lady Randolph Churchill, who, just on the eve of her departure for South Africa, which it is an open secret was mainly to bring her nearer to her only son, Mr. Winston Churchill, has received the news that he is wounded and a prisoner in the hands of the Boers.

The smallpox epidemic at Hull still continues slowly but obstinately to persist and spread in a most annoying manner. The new smallpox hospital is being rapidly

filled by fresh cases, one of which has actually developed in a prisoner confined in the jail. This starts a new focus for possible spread of the infection.

The committee of the Local Government Board on the use of preservatives and coloring matters in food, has again commenced its sessions under the presidency of Sir Herbert Maxwell, M.P. Representatives of the trade called before them frankly admitted that various matters were used purely for the preservation or even simply for the beautifying and rendering more attractive to the eye of articles of diet. The use of sulphur in the bleaching of raisins, plums, and apricots, which is so widespread on our own California-fruit farms, was defended on the ground that it greatly improved the appearance and the flavor of the fruit without in any way detracting from its digestibility, although one of the witnesses admitted that sometimes in the case of plums a trace of it was distinguishable to the palate. The same useful bleaching substance is used in the French bottled mushrooms, of which it is actually alleged to improve the taste. More serious was the admission that all green preserved vegetables have their color fixed by sulphate of copper, especially in the case of peas, beans, and spinach, vegetable coloring having been tried and failed, and the dealers frankly declare that the products were unsalable without this fresh green tint. They have actually attempted to introduce the uncolored vegetables at various clubs and restaurants, with the result that although the proprietors and managers are anxious to use them, customers to whom they were served sent them back to the kitchen. This is not a pleasant state of affairs, and it is the duty of the profession to educate the public up to the dangers involved and the foolishness of insisting upon having food material that is pleasant to the eye no matter what the risk. The sulphur-bleached dried fruits, while probably in no way poisonous, are leathery to a most indigestible degree, and while, of course, the amount of sulphate of copper used in the coloring of green vegetables is probably not sufficient to produce toxic effects, yet there is no telling what cumulative results may ultimately develop from prolonged use of such "blue-vitriol" goods.

A most unusual case was presented at the surgical clinic of the Medical Graduates' College this week through the kindness of Dr. Macnamara. This was an Egyptian giant alleged to be seven feet eleven inches in height, and looking every inch of it. Like nearly all these prodigies who exhibit themselves before the public, as he had done with Barnum and Bailey for the past year, he declined to submit to exact measurements, alleging in broken English that he thought it was unlucky, possibly with a fear that, as the Irish superstition has it, he would not grow any more afterward. But by checking off his height against a high door-post and measuring the result, it seemed positive that he was about seven feet two inches. His legs and arms were both enormously long, the crest of the ilium reaching to the shoulder of a man of average height. His cranium was in no way above the average size, while his jaws were large and his hands and feet enormous. Thus there would appear to e at least a suspicion of an acromegalic element in his giantism. His general health, however, was excellent, and he presented no other abnormality whatever with the exception of a large cystic tumor in the front of the neck, which was regarded by his physician as probably a hygroma or congenital cyst. He is only twenty-three years of age, and we wish him a long life and much fame, but it is to be hoped that when he joins the majority an examination of his pituitary body and fossa will be able to be secured.

The formal annual meeting of the Fellows and Members of the Royal College of Surgeons has been held, and, as was expected, proceeded to take some decidedly vigorous action, condemning the Council for its refusal to include in the application for the new charter a clause granting some form of representation at its Board to the members of the College. After a vigorous discussion this resolution of regret and request for amendment was passed by the large majority of 42 to 6. But as the Council is as independent of the annual meeting and its wishes as is the General Medical Council of those of the British Medical Association, we fear there is little likelihood of this reprimand producing any effect. Besides, it must in fairness be admitted that while the demand of the members is an eminently just and moderate one, yet the fact, that out of their thousands only forty-two thought it worth while to attend the meeting, would scarcely seem to indicate that the mass of them are very seriously concerned about their disfranchisement. At least, so we fear, will these figures be regarded and used by the Council.

Another gratifying instance of the way in which nations, however hostile otherwise, can unite in the humanities of medicine is furnished by the recent donation of large quantities of equipment and supplies for the British wounded in the Transvaal, from the French, German, and the Italian Red-Cross Societies. The former has already offered complete equipment for two field hospitals to the English authorities, and this has been gratefully accepted. This is one of the memories of Sedan which brings nothing but pleasantness with it, and it is doubtless connected in some degree with the appointment of Sir William MacCormac, who was the general director of the Red-Cross forces in that campaign.

The law has a curious way in England of insisting upon being obeyed even by quacks. Another case against the vendors of an abortifacient remedy, a faint shadow of the celebrated Chrimes Brothers' affair of a year ago, is now being tried in one of the higher courts. The concern entitles itself "The Herbal Institute," and its methods were the familiar ones, the original departure being that of vending its nostrums from house to house by women agents dressed as hospital nurses, which was a distinctly ingenious ruse. The evidence seems sufficient to render conviction of all five of the defendants highly probable.

The rôle played by the profession in civic and political life in this country is steadily increasing. In the late municipal elections no less than thirteen towns in England and Wales elected medical men as mayors, two or three of the most prominent members of the admirable London

County Council are physicians, and the profession is well represented in the House of Commons.

A suggestive illustration of one of the secrets of the inexhaustible colonizing powers of England is afforded in rather a mournful manner this week by the death of a Welsh collier who could actually count half as many children as he could years of life, twenty-two and forty-four respectively. Larger families than this have, of course, been frequently reported, but we doubt if a similar proportion at an earlier age has as yet been placed on record. The poor fellow was found drowned in a pond, and he was stated to have been much depressed for some time previously, though whether the size of his group of progeny had anything to do with his depression was not stated.

SOCIETY PROCEEDINGS.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Proceedings of the Twelfth Annual Meeting, Held at New Orleans, La., December 5, 6, and 7, 1899.

DECEMBER 5.—FIRST DAY.—MORNING SESSION.

THE Association met at the St. Charles Hotel, and was called to order by the President, DR. JOSEPH TABER JOHNSON of Washington, D. C.

An Address of Welcome was delivered by DR. HENRY DICKSON BRUNS on behalf of the local profession, which was responded to by PRESIDENT JOHNSON.

DR. ERNEST S. LEWIS, Chairman of the Local Committee of Arrangements, made a brief report of the work of the Association.

The first paper read was by DR. A. M. CARTLEDGE of Louisville, Ky., entitled

MYOMATOUS TUMOR OF THE EXTERNAL ILIAC VEIN, WITH REPORT OF A CASE.

Myomatous tumors arising from the muscular coat of veins constitute one of the rarest of pathological curiosities, as a faithful search of the literature by the essayist discovered but two reported cases. A brief account of these was given. His own case occurred in a woman, aged fifty-three years. Five years ago the patient suffered from swelling of the left limb, extending from foot to hip; it came on gradually, and the limb attained a considerable size; the swelling subsided in eight or ten months. She had pain at this time in the left iliac region. No enlargement was noticed. Two years ago the patient noticed a small lump just above Poupart's ligament on the left side, from which she suffered some pain. Within the last year pain has been much greater in the left iliac region, enlargement more distinct and very hard; latterly she lost much flesh; slept poorly on account of pain, and also suffered from accumulations of gas in the bowels. A diagnosis of carcinoma of the deep inguinal glands above Poupart's ligament was made. Exploration of the iliac tumor was advised for a more positive diagnosis, and removal if found expedient. This was accepted, and the operation performed on March 9, 1899.

Operation consisted of an incision beginning near the external abdominal ring, and running one inch above and parallel with Poupart's ligament, five inches in length, which came in contact with the tumor after opening the fascia of the external oblique muscle. The anterior part of the tumor occupied the inguinal canal; the round ligament was easily identified in front of the tumor occupying the most fantastic relation to it, wound as it was in and out around several lobules of the tumor; it was separated easily and pushed to the inner side. By blunt dissection it was gradually freed from its upper and lower and external bed. The outer and deeper attachments were approached with great concern, as they were evidently in the closest relation with the external iliac vessels. Gentle and careful blunt dissection carried the pelvic peritoneum upward, no button-holing of the same occurring. After reaching the base and upper and outer part of the growth the external iliac artery could be plainly felt entering the tumor. Search to the inner and posterior aspect of the artery failed to demonstrate definitely the vein, nothing more than a fibrous thickening could be made out, which was lost in the tumor substance. The tumor was separated from above downward, the deepest projection being disembedded from the obturator foramen; it now remained only attached to the vein and artery beneath Poupart's ligament. These were freed from the surrounding structures by blunt dissection, and were ligated separately and the tumor removed. In cutting the vein below where it entered the growth it was manifest that its lumen was almost obliterated, barely admitting a good-sized needle. The tumor was removed entire, and passing through it and removed with it was one and three-quarter inches of the external iliac artery, and the same length of the nearly obliterated vein. The only hemorrhage of any account was from the obturator vein where it passes through the foramen; this was easily secured by ligation. The upper portion of the incision was closed by tier sutures, the lower portion left open and drained with gauze. Patient is progressing toward recovery.

DR. WILLIAM E. PARKER of New Orleans referred to the difficulty of diagnosticating tumors below the groin.

DR. J. WESLEY BOVEE of Washington, D. C., followed with a paper, entitled

URETERECTOMY.

He said that surgery of the kidney was practically of recent date, and surgery of the ureter was the logical sequence to renal surgery. The paper considered essentially the subject of ureterectomy, an operation less than nine years old, one seldom indicated, but offering brilliant results. Dr. Bovee reported the following case:

Mr. J. J. T., forty-eight years of age, was first seen with Dr. E. Reisinger of Washington in August, 1898. Three years previously his left kidney had been removed for a renal abscess, and subsequently another operation had been done by the same surgeon for the remaining pus tracts and for severe localized pain. He had never been without pain, and was frequently obliged to resort to the use of morphin. The patient was in a very much

enfeebled condition, his pulse ranging from 110 to 130, and his temperature from 99° F. to 101.6° F. On the left anterior and lateral aspects of the abdomen, slightly below the level of the umbilicus, were two scars of the previous operations. A large hernia had occurred. There were three sinus tracts in the left lumbar region discharging thin, watery pus. In spite of the general weakness of the patient an exploratory operation was advised, which was done on August 17, 1898, with the assistance of D. Reisinger. By careful dissection and holding probes in the fistulæ the former location of the kidney was reached. Instead of the kidney a large amount of adipose tissue, containing many pus tracts and calculi and much cicatricial tissue, was found, and a little below it the upper end of the ureter surrounded by calculi and thickened pus. The ureter was about one inch in diameter, and filled with cheesy pus and calculi. Dr. Bovee resolved to remove the duct, and immediately extended the incision to the inguinal canal, keeping about one inch from Poupart's ligament. With considerable difficulty, but with very slight loss of blood, the ureter, in pieces, was removed to the bladder wall. The distended lumen ended abruptly about half an inch from the bladder-wall, this portion being a solid cord. The wound was closed with through and through silkworm-gut sutures, a strip of iodoform gauze being passed to the lowest point of the pelvic wound and brought out at the lower end of the external incision, and another strip in the space formerly occupied by the kidney. The unusual atmospheric high temperature and humidity probably assisted in producing a fatal issue seventeen hours later.

DR. SAMUEL E. MILLIKEN of Dallas, Texas, called attention to a point in technic adopted by Kelly, namely, instead of making one incision he leaves a bridge of abdominal wall, making the first incision from the twelfth rib down to the crest of the ilium in front of the lumbar muscles, with a second incision along the inguinal region. This enables the operator to expose the kidney, to make a thorough examination, and also to trace the ureter.

DR. BOVEE, in reply to Dr. Milliken, said there might be the advantage in two short incisions by having a less amount of tissue to cut across, as muscles, fascia, etc., over one large one, but he thought there was a drawback in having to dissect through a smaller space to loosen the ureter between the two incisions. Such an operation would require more time which, in many instances, is a precious element. However, he was not disposed to criticise Dr. Kelly's method because he had never tried it.

SERIOUS COMPLICATIONS FOLLOWING PASSAGE OF THE URETHRAL SOUND.

DR. WILLIAM E. PARKER of New Orleans read a paper with this title. He reported the case of a man with stricture of the urethra who passed urine with difficulty. The first time a sound was passed he had a chill, with a temperature of 105° F. After a week the sound was passed again, with no fever having occurred between the days of passage of the sound. In the meantime, the man's urine was examined, with a report showing the specific gravity to be 1020, half per cent. of albumin, no casts nor pus, and acid reaction. After the passage of the sound the second time the man had a urethral chill, suppression of urine, and died with uremic convulsions the following day, that is, the second day after the passage of the sound, although the usual precautions had been taken to prevent urethral chill. The autopsy showed that there was intense congestion of both kidneys, with pus in the pelvis, and in the calices of the left kidney.

DR. WM. P. NICHOLSON of Atlanta had seen a number of cases of severe chill following the introduction of sounds where all the necessary precautions had been taken. He had observed six cases of swelled testicle following the introduction of the sound, but had not seen a fatal case. In a book on the "Calamities of Surgery," Sir James Paget mentioned a case where the introduction of the catheter caused suppression of urine and death of the patient. The experience of genito-urinary surgeons would show, no matter how careful they were in sterilizing instruments, etc., in many cases the apparent nervous connection between the organs would produce a severe chill, and, in some cases, suppression of urine.

DR. W. F. PARHAM of New Orleans believed that post-mortem examinations would show, in cases where death had occurred after the passage of the urethral sound or catheter, some form of nephritic trouble, usually the interstitial. He racalled the case of a man upon whom he had operated for strangulated hernia, who had given no history of any renal trouble, yet the patient died of interstitial nephritis, as verified by an autopsy.

DR. MANNING SIMONS of Charleston, S. C., said he had met with a number of cases in which the passage of the sound was followed by trouble. It is his routine practice, when a man presents himself for the first time, in whom he has to pass the sound, to administer a grain of opium, and 10 grains of quinin immediately after its passage as a prophylactic measure against urethral chill and fever. He thought the cases should be divided into three classes. First, those in which the trouble is reflex from the nervous system; second, those in which urethritis is set up by unclean sounds, and, third, those in which there is serious disease of the kidney, but not discovered, preceding the use of sounds.

DR. J. D. BLOOM of New Orleans narrated two fatal cases from the passage of the sound in New Orleans, and these showed kidney lesions post-mortem.

DR. F. W. MCRAE of Atlanta reported a fatal case which occurred in the practice of the elder Westmoreland while the speaker was a medical student. He had seen complications follow the introduction of the sound. During the last five or six years he had not introduced a sound, except in the direst emergency, without having the patient under observation for several days thereafter. His results had been better since paying particular attention to careful preparation of the patient, instruments, repeated examinations of the urine, etc.

GUNSHOT WOUNDS OF THE ABDOMEN.

DR. H. H. GRANT of Louisville, Ky., read this paper. He said that the surgery of gunshot wounds of the abdo-

men, which had been for some years pretty well settled to the satisfaction of the profession, received something of a shock by the report of the surgeons who served in the late war with Spain. (*Journal American Med. Association*, July 11, 1898.) Though these reports, which were made by men of experience and high reputation on the subject, were modified to bear especially on the wounds received in battle, yet the inferences, and indeed the conclusions, affected surgical judgment to a considerable degree. The results of the investigation of Klemm show in an analysis of 152 cases that in nearly all of those in whom penetrating wounds of the abdomen were established, who did not die of immediate effects, eventually succumbed to exhaustion from sepsis, and later from suppuration. The meaning of this was that, practically speaking, all penetrating gunshot wounds of the abdomen, untreated by surgical repair of the lesion, die either of hemorrhage, peritonitis, or sepsis. The mortality after operations done in the first seven hours after injury is fifty-two per cent., as against sixty-four per cent. for operations at all periods. But a study of the tables of Parker shows such variations in the mortality succeeding complicated and uncomplicated wounds of the various viscera, all of a fatal character without operation, as to indicate that in uncomplicated wounds in some situations the early operator will save from seventy-five to eighty per cent. of what would otherwise be fatal cases. His tables also show that of 16 operations done, in which no intraperitoneal injury was found, but 3 died, 1 from an overlooked perforation and 2 from peritonitis, due to infected blood-clot, a fatal complication upon which Klemm lays so much stress.

Dr. Grant sent out a circular-letter to 100 prominent surgeons, and an analysis of the reports developed a number of most important and interesting facts. The mortality in the whole number of operators was about fifty-two per cent., an indication that the prognosis is improving with the more energetic measures of treatment. The practical management of suspected penetrating wounds is as plain a duty as the tying of a bleeding artery. As soon as possible after the injury the patient should be transported to a suitable place, and, under aseptic precautions the experienced hand should carefully trace the course of the bullet into the cavity. This is easy enough when the penetration is direct from the abdominal wall, but often difficult or impossible when from behind or from the thoracic or pelvic cavity. Under these latter circumstances the history of the direction of the projectile, and the general symptoms must be the guide, giving to the side of operation the benefit of thedoubt.

DR. HUGH M. TAYLOR of Richmond, Va., said he had operated on three cases of gunshot wounds of the abdomen within the last two or three years. He laid stress on the utter hopelessness of cases until an operation was done. Of course, he was aware that arguments had been advanced by good men against surgical interference in many cases. It is not always easy to satisfy the attending physician, in the absence of serious symptoms, that an exploratory incision is imperative. Of he three cases narrated by him, one was saved.

DR. WILLIAM E. PARKER was glad to note that the percentage of recoveries from operative interference in gunshot wounds of the abdomen is improving. Cases occurring in civil life should be operated on as soon as possible. In military life he had taken the stand that with the modern small-calibered bullet, as many cases would get well without operation in the field as with it. He mentioned a case operated on by the late Dr. Miles in which there were fourteen intestinal perforations, which were closed, and the patient recovered.

DR. MANNING SIMONS had operated on twenty cases of gunshot wounds of the abdomen by laparotomy, and of this number he saved three. One was a gunshot wound of the stomach, the operating having been done within a few hours after the occurrence. There were two perforations, one of entrance and one of exit, the bullet having lodged in the muscles of the back. This patient, a boy, recovered, and is well to-day. In one of the cases there were fifteen perforations of the bowel. In some he had resected as much as two feet of the small intestine.

DR. SAMUEL E. MILLIKEN had encountered one case of gunshot wound of the abdomen in a child, seven years of age, who had received the contents of a shotgun. He performed a laparotomy, and the child recovered.

DR. J. D. BLOOM said the diagnosis of penetrating wounds of the abdominal viscera was very essential in deciding on an operation. He mentioned the case of a man who was brought into the Charity Hospital, where it was thought that the peritoneal cavity had been penetrated, but laparotomy disclosed that there was no penetration. He recalled a number of cases that recovered when the operation was done within twenty-four to thirty-six hours after being shot.

DR. W. E. B. DAVIS of Birmingham, Ala., said the question to be settled was whether every case of penetrating wound of the abdomen should be operated on. He believes that every such case should be so treated. He condemned the Senn gas test, and said that the teachings of this eminent surgeon in regard to gunshot wounds of the abdomen were harmful in that they had created a sentiment which made it exceedingly difficult in certain communities to operate on cases of penetrating wounds of the abdomen, because if the patient should die the surgeon would be censured, and discredit cast upon surgery.

DR. F. W. MCRAE had seen and operated on five cases of gunshot wounds of the abdomen at the Grady Hospital. The point of entrance of the bullet was above the umbilicus, the injury having been received when the patient was standing, and in every one of them there were numerous perforations of the hollow viscera. In military practice, he said, wounds were received by soldiers who had been fasting for a number of hours, and the intestines were empty; extravasation was not so likely to occur. On the other hand, in civil practice wounds were almost always received under conditions of more or less debauchery, when the stomach was loaded with whisky, beer, food, limburger, etc., consequently extravasation of the contents took place rapidly, and death was much more apt to take place. He considered the Senn gas-test

worse than useless, it being merely corroborative, not conclusive as to penetration of the viscera.

DR. GRANT, in closing, said he had enunciated a few surgical principles, and he hoped the Fellows would conclude that it was the duty of the surgeon to operate as much on a penetrating wound of the abdomen as it was in cases of strangulated hernia.

FIRST DAY—AFTERNOON SESSION.

DR. RUDOLPH MATAS of New Orleans presented a paper in which he gave the history of pulmonary insufflation and artificial respiration in intrathoracic surgery by intubation of the larynx, exhibited an apparatus, and demonstrated its application. In summing up the peculiarities of the apparatus he had shown he called attention to the following points: (1) The original O'Dwyer cannula, while retaining its intralaryngeal portion unchanged, is modified so that it may be utilized, first, as a respirator; second, as a tampon cannula; third as an anesthetizer; fourth, as a tractor and tongue; fifth, as an insufflator; sixth, as an aspirator.

(To be Continued.)

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, November 2, 1899.

THE President, DR. WILLIAM H. THOMPSON, in the Chair.

The paper of the evening, read by DR. ANDREW H. SMITH, was entitled

THE TREATMENT OF PNEUMONIA AS BASED UPON ITS RECENT PATHOLOGY.

It will be found on page 777 of the present issue of the MEDICAL NEWS.

The discussion of the paper was opened by DR. FRANK W. JACKSON, who said: We are practically agreed that there is no specific for pneumonia. All of the many remedies that have been recommended are about equally good. A reports 106 cases cured by one method. B goes him one better and reports 107 cases treated by a diametrically opposite method with equally good results. It is not the pneumonia that is to be treated; it is the individual in each case to whom it is important to adapt our remedies. I am myself a pupil of Dr. Leaming, and I believed for a long time in the efficacy of very large doses of calomel, 30, 40, even as high as sixty grains. It certainly never seemed to do any injury, and the patient often sank into a quiet slumber shortly after its administration. A temperature of 105° F. would fall to 101° F.; a restless patient would be quieted, but in twelve hours all the symptoms had reasserted themselves, and the calomel often refused to work as favorably the second time. Three years ago I treated an old man who had a severe case of pneumonia with ¼-grain doses of calomel, and they seemed to have as good an effect as the large doses of years ago.

I think it is hopeless to try to abort pneumonia even if we reach the case after it has been in progress for only five or six hours. No method of treatment will accomplish this. At Roosevelt Hospital twenty years ago large doses of quinin internally and an oiled-silk jacket externally constituted routine treatment. If a member of the staff came along and found one of his patients without this combination treatment there was a row. Yet after a good trial of this method in a hospital where patients can be seen often it was given up as ineffectual.

As to creosote, there is not so much to be said in its favor more than for either calomel or quinin. I have never found it to do much good in tuberculosis, and have never noticed any benefit in pneumonia. It is of benefit in bronchitis. It softens the cough, and this is the secret of its influence in tuberculosis. I have had very little experience with the salicylates. When pneumonia comes, however, it does not announce how long it is going to last, and so we can not be sure of the effect of any given remedy. The crisis may occur thirty-six hours after we begin any treatment. It may occur twenty-four hours after acute symptoms have set in without any treatment. I would like very much to have Dr. Smith's faith in the possibility of creosote aborting the disease if taken early enough, but I have not.

In some cases scarcely more treatment is required than for a simple fever, and active treatment would do harm. In some patients there is intense prostration and septic fever from the very beginning. In these stimulants and digitalis for the heart are very good, though this latter drug should not be used unless absolutely required. In other cases restlessness is the main feature. Then opium is advisable, though this is not recommended in the text-books.

DR. ALFRED MEYER said: The principle to treat the patient not the disease in every affection is the only one worth any consideration from a rational physician. This fact to-night's discussion promises to bring out very clearly. The pathology of pneumonia as presented by Dr. Smith is most fascinating. Yet I do not agree with his conclusions in the matter. Dr. Smith insists that if pneumonia were really an inflammation of the lungs, a genuine pneumonitis, it would not get better so rapidly, and it would leave more lasting changes. It must be remembered, however, that inflammations differ very much in different tissues, and that the picture presented in the lungs will be necessarily very different from that which would be observed in a more solid organ. There is no doubt that changes of a substantially inflammatory character occur in the cells lining the alveoli sufficient to stamp the affection as an inflammation. As to the necessity for permanent changes in the tissues after inflammation, it must be remembered that such characteristic inflammations as erysipelas of the face or sun-burn recover without leaving permanent tissue changes. There is no doubt for other reasons that pneumonia is a true inflammation of the lungs. By continuity the pleura and the pericardium may also become infected, and in these structures the pleurisy and pericarditis that are set up are surely of an inflammatory nature.

As to the treatment of inflammation, it is hard to say anything definite. There are cases that run a very brief course, and any remedy that is given will seem to have

aborted the inflammation. In my own experience large doses of salicylates have given me the best satisfaction in the treatment of pneumonia. I consider this drug much better than digitalis, which is so highly recommended by Petrescu. Petrescu shows a good set of statistics treated with digitalis, but all his cases occurred in young soldiers, the picked men of the country, and practically any method of treatment, or even no treatment at all, would have given as good results.

At Mt. Sinai Hospital results have improved very much in the past ten years in the treatment of pneumonia. While in 1887 the death-rate was thirty-seven per cent., in 1897 it was scarcely more than eight per cent.

DR. CHAPIN said: In children the main symptom of pneumonia is the toxemia that so often is developed. In children the right heart is comparatively very strong, and as a consequence one does not often see the symptoms of dyspnea which are so common in adults. This is probably the reason why so few cases of croupous pneumonia are fatal in children, and this seems a rather strong argument against the efficiency of specific bacteriologic treatment. If we can but strengthen the right heart sufficiently to enable it to overcome the obstacle to the circulation in the lungs the patient's safety is assured. I previously used creosote, but have abandoned it. I have found that the presence of steam in the room is of great service. It especially lessens the tendency to the hacking cough which is sometimes so hard to control. I have found plain steam quite as efficient as any medicated vapor. I have often used nitroglycerin, and have been very well satisfied with the results. Dr. Smith's teaching as to the pathology of pneumonia will undoubtedly do good if for no other reason than its suggestiveness. The principle of the germicidal treatment does not work well in practice. All germicides are depressant. For this reason I do not like large doses of salicylates nor of calomel. The fact is that in certain years we see a series of much severer cases of pneumonia than in other years, cases that are of the septic type from the beginning, that are modified by secondary infection, that have an influenza element in them, and these are not relieved by large doses of antiseptics.

DR. EDWARD K. DUNHAM said: I should regret very much to see pneumonia taken from the list of inflammations, for I am accustomed to demonstrate it to my class every year as an example of acute exudative inflammation. There is no essential difference between the inflammatory process of acute lobar pneumonia and that of acute pleurisy, or of lepto-meningitis. Under the microscope one cannot be separated from the other. The same process that occurs in the whole lobe of a lung in pneumonia occurs in small foci of pneumonic tissue after other irritative agents. Good examples of this may be seen around a tubercular nodule in the lung or in the neighborhood of a hemorrhagic infarct. Not only does the exudation show that there is a genuine inflammation, but also the reaction in the cells of the alveolar walls proclaims the same fact. I have here under microscopes four specimens; first, a section of pia mater affected by fibropurulent lepto-meningitis; second, croupous pneumonia; third, the alveolar wall of a lung with an increase of tissue under rejuvenescence of the cells, and, fourth, an alveolar wall from a case of edema, without any inflammatory production of tissue. I think that a glance at these specimens will show how closely pneumonia resembles the processes which all admit to be inflammatory, and how different it is from those in which there is no inflammation. In pneumonia the cells take on certain very characteristic inflammatory changes. The nuclei become enlarged, the chromatin is increased, and the cells generally are in a plastic state. With reference to the clots that are often found in the pneumonic vessels post-mortem, it is more than probable that these have been formed after death. In a case of pneumonia all the elements for fibrin formation are abundantly present, and a stoppage of the circulation would be the signal for the exercise of this property.

DR. WILLIAM H. THOMPSON said: It is very interesting to contrast typhoid fever and pneumonia, the two most fatal diseases of mid-life. In both diseases patients die of toxemia. In both the prognosis of the case depends to a large extent on what the patients take into the disease with them, that is, the condition at the beginning of the illness is the important element in the prognosis. There all similarity stops. Typhoid gets better by lysis; pneumonia by a typical crisis. We have learned so to treat typhoid that the death-rate is comparatively low. Of 344 cases that have been in my care for more than a week at the Roosevelt Hospital only three per cent. died. Pneumonia is very different, and one seems almost perfectly helpless in the presence of certain severe cases. We must look for an antitoxin for the disease. Its self-limitation points to the fact that an antitoxin really exists. Despite failures I believe that it will yet be found. We certainly have as yet no specific remedy.

I believed for a time that I had found a specific for pneumonia in the internal administration of chloroform, and still believe that 30 minims of chloroform administered at the time of the chill will often abort a threatened pneumonia in a few hours. I first tried the remedy on a series of ten cases of the unfavorable kind that come to Bellevue, men whose systems are thoroughly broken down by the use of alcohol and for whom the prognosis as is well-known is unfavorable. Every one of the cases recovered though some of them seemed very unpromising at the beginning. I began to try it then in my private practice. Certain unpleasant symptoms occurred, however, and in two cases unaccountable sudden death occurred and so I have abandoned it. A combination of carbolic acid and chloroform constitutes the best remedy we have. It acts as a true germicide and does not seem to affect the vitality of the tissues at all. Recently in cases of double pneumonia I have had excellent success with 20-grain doses of creosote carbonate, creosotal, administered every two hours. A very palatable emulsion can be made of the drug and patients take it readily. I have recently had three most unpromising double pneumonias recover under this treatment. When there develops in double pneumonia the tracheal râle, which is usually so threatening a symptom and of sinister omen, I

have found that turning the patient over on the abdomen and making pressure on the back relieves the symptoms at once.

DR. CROOK said: Pneumonia has the typical signs of an inflammation. The color, dolor, tumor, mentioned by Galen are all present besides a fibrinous exudation, which combine to show that an inflammatory process has been at work in the tissues. The fact of its complete resolution rather confirms its designation as an inflammation than argues against it, since all mild inflammations, bronchitis, pharyngitis, and the like undergo resolution without leaving structural changes behind. It is probable that in fatal cases not only is the pulmonary circulation affected by the inflammatory process in the pneumonia but that the bronchial circulation is also affected. Something that is not sufficiently borne in mind is that pneumonia like other inflammatory processes is often contagious. This the investigation of the British Medical Association some time ago showed very clearly.

DR. SMITH said in closing the discussion that no one in treating of pneumonia had ever before adverted to the double circulation in the lung. Volumes, even libraries, had been written on the subject without any consideration being given to this important fact which completely changes the conditions from those that exist anywhere else in the body. The pneumococcus produces inflammation of serous membranes, of the meninges of the brain, of the pericardium, of the pleura, but no crisis ever occurs in these cases. Pneumonia ends with a crisis precisely because it is situated as it is in the midst of the double circulation of the lung and practically outside of lung tissue. The germ is killed by the products of its own metabolism, by its own urine as it were. Of these products the principal ones that have been obtained by analysis are pneumic acid and pneumate of soda. These practically produce the crisis. Their accumulation in the exudate makes an acid medium on which the pneumococcus has to grow and the slightest acidity of culture medium, as is well known to bacteriologists immediately causes the death of the pneumococcus. This is the explanation of the crisis. It is not due to the inflammatory process having reached an acme with sudden subsidence, as some have explained. If a process so extensive and serious as is pneumonia were to occur in the delicate tissue of the lung it would surely leave more important permanent changes than are ever found after pneumonia. We would surely find such changes in the liver the kidney or the spleen. The reason why we do not find them in the lung is that pneumonia is not really an inflammation.

REVIEWS.

TEXT-BOOK OF THE EMBRYOLOGY OF THE INVERTEBRATES. BY DR. E. KORSCHELT, Professor of Zoology and Comparative Anatomy in the University of Marburg; and DR. K. HEIDER, Professor of Zoology in the University of Berlin. Translated from the German by Matilda Bernard. Revised and edited by Martin F. Woodward, Demonstrator of Zoology in the Royal College of Science, London. Vols. II. and III. London: Swan, Sonnenschein & Co. New York: The Macmillan Co., 1899.

IN Cassino's "Naturalists' Directory of the United States" the names of at least ten thousand persons interested in natural history subjects are given. Of these between ten and fifteen per cent. are physicians, and it therefore seems distinctly proper to mention in this place a work which is so essentially in the line of the naturalist. Korschelt and Heider's "Invertebrate Embryology" has been known for years among German-reading students of zoology as the standard text-book in this branch of research, and it is fortunate that the first volume, which appeared in translation in 1895, is now further completed by Volumes II. and III., because the many interesting problems of invertebrate embryology are now made accessible for the first time to the English student.

The present volumes are concerned mainly with the consideration of the developmental stages of the Bryozoa, Brachiopoda, Crustacea, Arachnida, Myriopoda, and Insects. For the technical student of embryology there is nothing to take the place of this excellent work and the natural historian of laboratory proclivities will find it a trustworthy guide as well as a stimulus to scientific research. The mechanical execution is of the well-known excellent quality of the publishers, to whom the technical scientific world has been so often particularly indebted.

THE DIAGNOSIS AND TREATMENT OF DISEASES OF THE NOSE, THROAT, NASO-PHARYNX, AND TRACHEA. For the Use of Students and Practitioners. By CORNELIUS G. COAKLEY, M.D., Professor of Laryngology in the University and Bellevue Hospital Medical College, New York. Illustrated. Philadelphia and New York: Lea Brothers & Co., 1899.

THIS manual of rhinology and laryngology, which is primarily adapted to the needs of the student, impresses one very favorably by the excellent way in which the entire field has been covered, without a single paragraph having been wasted on unessential details or on theoretical considerations. The introductory chapters on anatomy and physiology are brief and to the point; the author's style here, as indeed it is throughout the work, clear, terse, impressive. In the chapters on treatment a departure has been made from the usual presentation of the subject of therapeutics, and a wise discrimination and limitation of procedures to those actually approved by the author's experience is made evident. Where surgical intervention is advised the best operation is accurately but briefly described. A special chapter of practical importance has been added which deals with the different rhinological and laryngological remedies and the manner of their application. The drugs are classified according to their local action, and a number of useful prescriptions with the indication for their employment are given. The work is a convenient and inexpensive students' guide to the entire field of diseases of the nose and throat, which may be recommended as a complete and trustworthy summary of the subject.

THE MEDICAL NEWS.
A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXV. NEW YORK, SATURDAY, DECEMBER 23, 1899. NO. 26.

ORIGINAL ARTICLES.

SOME OBSERVATIONS ON MODERN CEREBRAL SURGERY.[1]

BY GEORGE EMERSON BREWER, M.D.,
OF NEW YORK;
ASSISTANT DEMONSTRATOR OF ANATOMY IN THE COLLEGE OF PHYSICIANS AND SURGEONS; ATTENDING-SURGEON TO THE CITY HOSPITAL; ADJUNCT-ATTENDING SURGEON TO MOUNT SINAI HOSPITAL.

Two factors have recently led to a radical change in views on the subject of opening the cranial cavity for purposes of exploration. The first of these is the success which has attended the general employment of perfected aseptic surgical technic, and the second, the great advances which have been made by neurologists and physiologists in the localization of cerebral functions. As the advances in these two departments occurred simultaneously it is not surprising that they led to an enormons increase in the boldness of surgeons in exploring the cranial cavity, and to an unwarranted amount of sanguine expectation on the part of the neurologists, who looked forward to the possibility of relief in a large number of conditions which had formerly been regarded as hopeless or necessarily fatal. I think I voice the sentiments of most surgeons of experience in this line of work when I say that up to the present time the results of exploratory cerebral surgery have been disappointing.

Since the publication of my last report I have operated three times, once in a case of cortical hemorrhage, once in a case of Jacksonian epilepsy, and once for the removal of the right Gasserian ganglion for persistent trifacial neuralgia. As the operation in the case of Jacksonian epilepsy was a secondary one to that originally reported in my paper as not improved, my experience to date covers twenty operations on eighteen patients. As a report of each individual case of my series would, I fear, prove a tiresome recital and would be practically a repetition of my previous paper I shall speak briefly of the different conditions requiring exploratory operations, reporting only a few cases for illustration.

Cranial traumatism, with or without fracture of the skull, as is well known, results in a number of conditions requiring prompt surgical interference. These conditions are hemorrhage, contusion, and laceration of the meninges or brain, as well as pressure from depressed bone or inflammatory exudates, and the secondary results of such injuries, as abscesses, cysts, areas of chronic meningitis, or cerebral softening. When these lesions occur over the motor area or other equally well-recognized centers, their diagnosis is a comparatively easy matter, but when present in other locations, as in the so-called silent areas of the brain, their diagnosis is often accompanied by great difficulty and embarrassment.

Without entering into a discussion of the surgical treatment of cranial traumatisms in general, the indications of which are doubtless well-known to all of you, I will simply state that when the patient survives the first shock of the injury death is usually the result not of the actual lesion produced, but of an infection which the nature of the injury favors. The logical treatment in these cases, therefore, when the possibility of infection is recognized, is an exploratory operation, and, if necessary, measures to prevent or combat sepsis. As an example of the untoward results which so frequently follow a failure to carry out this plan of treatment early, the following case, the third of my series, will be mentioned. The patient was a middle-aged man who had been injured by a fall causing a wound over the upper left quadrant of the occipital bone. As his injuries did not seem serious he was transferred from one hospital to another without treatment other than the application of a bandage until he finally reached the City Hospital several days after the injury. When first seen his mental condition was so sluggish as to preclude the possibility of eliciting any definite history. There was moderate continued fever, slow pulse and irregular pupils. He was seen in consultation by Dr C. A. Herter, who, although unable to arrive at any definite diagnosis, regarded the condition as one of grave intracranial sepsis, with the possible pressure of a cortical abscess at or near the site of injury. A large bone-flap was raised in the usual manner, including the fractured area and the injured dura. Great intercranial pressure was evidenced by the bulging of the brain through the open dura. A moderate amount of leptomeningitis was present, also a small cortical abscess, which was incised, and about a dram of creamy pus evacuated. Gauze packing, partial suture of the flap, and a layer of sterile gauze completed the dressing. No improvement in the patient's condition occurred. Death followed in two days, and the autopsy revealed a

[1] Read by invitation at the meeting of the Plainfield, N. J., Clinical Society, June 20, 1899.

general septic meningitis and distention of the ventricles with sero-pus.

From the examination at the time of operation and at the autopsy it was clear that this patient had sustained a simple depressed fracture of the skull with a slight wound of the dura, producing practically no cerebral symptoms until infection had spread over a considerable area. Had an exploratory operation been performed at once and the area carefully disinfected and properly drained the patient would undoubtedly have recovered promptly.

As examples of some of the remote effects of neglected cerebral traumatism I will give the history of two rather striking cases:

Case I.—A colored boy, age twenty years, was admitted to the hospital in January, 1899, suffering from rapid pulse, profound stupor, low delirium, and grave sepsis. Upon examination he was found to have the evidences of an active lung-tuberculosis. From his friends it was learned that he had sustained an injury to the skull in the upper middle frontal region some weeks before for which he had been operated upon at the hospital. Since the operation he had gradually become more stupid and irritable. A scar of a transverse incision was found over the center of the skull about one inch back of the margin of the hair. One inch and a half in front of this there was a boggy induration, which upon deep pressure gave the sensation of obscure crepitus. As the lad's condition was extremely critical he was prepared for operation before being seen by me.

Under chloroform anesthesia a longitudinal incision was made in the median line from a point one inch above the root of the nose to the center of the old scar. The periosteum was found to be thickened and edematous, and when incised and retracted the bone appeared spongy. A large trephine was employed over the center of this softened area and a button of bone carefully removed. The opening thus formed led to a cavity about the area of a silver half-dollar between the bone and the dura which was filled with thick curdy pus. The diseased bone forming the roof of this cavity was removed with rongeur forceps, the cavity carefully curetted, injected with a solution of formalin, and packed with wet formalin gauze.

The cerebral symptoms were promptly relieved, his temperature dropped to a degree or two above normal, his appetite returned and he began to improve rapidly. The first dressing was made on the sixth day, when the cavity was found to be perfectly clean. Later the wound was dressed with iodoform gauze and allowed to heal by granulation. His recovery from the operation was prompt, uneventful, and satisfactory. He was later transferred to another ward, where I have since learned he died of his tuberculous infection without any return of the cerebral symptoms.

Case II.—A young man, aged twenty-six years, was admitted to the hospital in January, 1899. December 16th, during a drunken brawl, he was struck on the forehead with an iron bar, after which he walked a short distance, but was finally taken to a hospital, where he remained sixteen days. Nine days after the injury he had a violent fit of muscular tremor lasting several minutes. Later he had five similar attacks, in some of which he lost consciousness. His temperature on admission was nearly normal. Upon examination a depressed and extremely painful scar was seen about two inches above the left orbit.

Under chloroform anesthesia an omega-shaped incision was made over the upper left frontal region extending well into the parietal bone, the base of which was directed forward to received the branches of the supra-orbital and temporal arteries. The bone was exposed and chiseled through in the line of the incision. On raising the bone-flap the inner plate was found to be fractured in such a way that two large, ragged fragments of bone penetrated the dura and were embedded in the first and second left frontal convolutions About one dram of pus was found between the scalp and depressed bone, and a large amount of grumous fluid in the cavity formed by the laceration of the cortex. The cavity was gently cleaned and packed with sterile gauze, the bone entirely removed, the dura united in part, and the wound dressed in the usual manner. No reaction followed the operation, and the patient has since been well.

As an example of an unusual result of cranial traumatism, the following case is reported:

Case III.—A man, fifty years of age, was admitted to the City Hospital in April, 1897, in a condition of marked mental torpor, rendering it impossible to obtain any history other than that he had been injured by a fall from a hay-loft. From the house-staff of Gouverneur Hospital, where he was treated, it was learned that he had fallen a distance of about fifteen feet, striking his head and inflicting a severe scalp wound over the left parietal region. The injury was followed by symptoms of shock which soon passed off, leaving him for a time fairly rational. Later he complained of headache, became feverish and delirious, and was transferred to the City Hospital.

Upon examination a partial paralysis of the right upper extremity, chiefly in the deltoid muscle was demonstrated. He was able to move the forearm and hand slightly. His pupils were equal and reacted slightly to light and accommodation. The pulse and temperature were moderately elevated. There was slight stiffness in the muscles of the neck, but no cranial nerve paralyses and no loss of sphincter control. He was seen in consultation by Dr. Joseph Collins, who was at first unable to arrive at a diagnosis. The symptoms, however, gradually became more marked, the mental stupor deepened; the paralysis became more pronounced and extended to the right leg, and the stiffness of the neck muscles diminished. After several days of careful observation Dr. Collins made the diagnosis of pressure over the left motor area from hemorrhage or a ser-

ous exudate, and advised an exploratory operation. Under ether anesthesia a large omega shaped bone-and-skin flap was raised. When the dura was incised there was a gush of about three ounces of comparatively clear fluid, leaving a large space between the dura and cortex. Upon further examination it was found that the depression in the cortex was limited and was apparently caused by the pressure of the fluid; it appeared as a circumscribed concave depression, the center of which was fully one inch from the overlying dura. The forefinger was introduced between the dura and pia, but no limiting adhesions were detected. The dura was partly sutured, a small gauze drain introduced, the bone-flap replaced, and the wound dressed in the usual manner. No systemic reaction followed the operation, but the patient's symptoms failed to show improvement. His coma deepened and he died five days later. Upon autopsy the wound was found to be free from infection. The brain and meninges presented nothing abnormal other than marked saucer-like depression over the middle and lower Rolandic area.

The propriety of exploratory operations in cases of traumatic and focal epilepsy has been extensively discussed, and a large number of operations have been performed, generally with disappointing results. The consensus of opinion among neurologists and surgeons at present seems to be that such operations are indicated only in recent cases, within one year after the injury, in cases in which general epilepsy has followed, and in cases in which the attacks are of a purely focal or Jacksonian type, especially if an injury has preceded and corresponds to the motor center presiding over the muscles which are the seat of convulsive movements. The reason that the operation does not give permanent relief in cases of long duration is explained by the theory that the epileptic habit has become established, or that cortical degeneration has taken place which relief of the superficial irritation does not remove. In these cases extensive cortical excisions have been suggested but as yet the number of cases in which this has been done has been too small to give any positive results.

I have selected three from my eight cases of epilepsy which may serve to illustrate these statements:

CASE I. *Old Traumatic Epilepsy.*—A man, twenty-six years of age, had sustained an injury five years before resulting in a marked depression of the skull near the upper anterior angle of the left parietal bone. Previous to this he had enjoyed perfect health. Following the injury, however, epileptoid convulsions had occurred and increased in frequency to such an extent as to render him a hopeless invalid. As the convulsions frequently began by violent lateral movements of the head to the right, and as the seat of the injury was over the posterior extremity of the first left frontal convolution, by the advice of Dr. E. D. Fisher, attending neurologist to the hospital, who saw the patient in consultation, an operation was undertaken. A large omega-shaped incision was made over the motor area, extending to the posterior margin of the depression. The bone, still adherent to the soft parts, was chiseled through and broken off in the usual manner. At the point of greatest depression of the inner plate of the skull the dura was found to be firmly adherent and thickened. This was separated and the depressed bone removed by rongeur forceps. The dura was then opened by a semicircular incision and the motor tract exposed. Nothing abnormal was found. The arm and face centers were verified by electrical stimulation applied directly to this region by Dr. Fisher. The dura was united by fine catgut, the bone replaced, and the soft parts sutured A sterilized gauze and cotton dressing was applied. The recovery was uneventful. The wound was dressed on the fourth day, and half the cutaneous sutures removed, and again on the fourteenth day, when the entire wound was found to have united by first intention.

Although the fits ceased entirely for several weeks, they recurred finally, though with less frequency. A recent report from Dr. Spratling of the Craig Colony, where he was afterward sent, states that his condition was practically the same as before operation.

CASE II.—*Recent Traumatic Epilepsy*—A lad, eighteen years of age, was admitted to the hospital suffering from epilepsy of several months' standing, following an injury to the right side of the head which resulted in a well-marked area of depression over the anterior and upper portion of the right parietal bone. The symptom which at first began as an occasional attack of Jacksonian epilepsy of the left arm and hand, had become more frequent, had changed from a mild local to a severe general type, and practically precluded the possibility of any regular employment. As the symptoms were distinctly focal at first, and as the duration was less than one year, the case was regarded as a particularly favorable one for operation. At the urgent request of the lad, therefore, after fully explaining the uncertainties of the result, an osteoplastic resection was made over the right parietal region including the area of depressed bone.

Upon raising the flap a moderate amount of depression was found to exist in the inner plate, causing a slight indentation of the dura. As there was no evidence of dural injury and no sign of an inflammatory deposit the dura was not opened The depressed bone was removed, the flap replaced and united by silkworm-gut sutures, and the head dressed in the usual manner. No reaction followed the operation. The first dressing was made on the fifth day, when the wound was found to be perfectly united. The patient was up and about the ward in three weeks, and after a month was employed as helper in the hospital. At the time of his discharge, about six weeks after the operation, he was apparently well, having had no epileptic symptoms since operation.

CASE III. *Traumatic Epilepsy with Partial Paralysis of Arm and Leg.*—Colored boy, twenty-one years of age, was admitted to the hospital in January, 1899, suffering from frequent epileptic convulsions, beginning invariably in the right hand and arm, extending to the right leg and finally becoming general, with complete loss of consciousness. He was somewhat uncertain as to the duration of these symptoms, but insisted that they followed an injury to the left parietal region from being hit by a stone. During the previous few months he had noticed a progressive weakness in the right arm and leg. He walked with some difficulty and the grip of the right hand was extremely weak. He complained of dimness of vision, but an examination of the eyes by Dr. Straus was negative.

Although I was unable to obtain the advice of a neurologist in this case the symptoms led me to advise an exploratory operation, which was accepted by the patient after a candid statement of the uncertainties of the result. An osteoplastic resection of the skull was made over the left motor area, and the dura freely opened. A large inflammatory exudate was found between the dura and the pia, firmly uniting these two structures and extending for a considerable distance below and on each side beyond the limits of the opening in the skull. Above the upper border of this exudate the brain bulged considerably and was of a dark-bluish color. This region was explored in several directions to a depth of two or three inches with a probe director with a negative result. An attempt to separate the dura from the pia over the area of inflammatory exudate resulted in such free hemorrhage that further effort in this direction was abandoned, it being necessary to ligate one of the pial arteries by passing a ligature on a curved needle through the cortex in order to arrest the hemorrhage. After complete hemostasis had been secured the flap was replaced and sutured, the usual dressings were applied, and the patient placed in bed. No reaction followed the operation, the wound united primarily, and the patient was about in three weeks.

As it was impossible in this instance to remove the lesion but little hope was entertained of any improvement in his condition. Much to our surprise, however, a few weeks later the patient began to show some improvement in walking and in the use of his hand. The epileptic seizures, at first apparently less frequent, soon became more marked both in severity and in frequency, occurring several times during the twenty-four hours. He was seen in consultation by Drs. E. D. Fisher and Joseph Collins, both of whom advised large doses of iodid of potassium on the theory that the inflammatory exudate might be of syphilitic origin, after which if no improvement followed an extensive cortical excision might be tried. The suggestions were carefully carried out for six or eight weeks without any improvement in the epileptic symptoms. In May last he was again anesthetized, a larger bone-flap raised, the dura incised, and the entire cortical region covered by the exudate, about the size of a silver half-dollar, removed to a depth of about five-eighths of an inch. No reaction followed the operation and the wound healed by first intention. There was, however, a marked increase in the paralysis of the leg and arm. The fits continued for a few days with about the same frequency then increased to such an extent that he had forty or fifty a day. About the third week after the operation they suddenly ceased and he has since been entirely free from them. The paralysis is slowly improving and the patient expresses himself as feeling exceedingly well.[1]

I have had but one case of tumor of the brain in which operation has been performed, but as that was an extremely interesting one the history will be briefly referred to. Although this case has already been reported by Dr. Collins and myself in the *Medical Record*, May, 1897, a brief résumé of its main features may not be out of place:

The patient, a man aged twenty six years, was admitted to the hospital in January, 1897, suffering from severe constant occipital headache, persistent vomiting, marked dizziness, and staggering gait with impairment of vision, the duration of symptoms having been about four months. He was immediately seen in consultation by Dr. Joseph Collins, who watched him closely and directed his treatment for six weeks, during which time he became progressively weaker and exhausted from constant pain and inability to retain nourishment. There was at no time any distinct cranial nerve-paralysis, anesthesia, hyperesthesia, or impairment of taste or smell.

The knee-jerks, at first present, gradually diminished and became entirely absent. There was slight ataxia of the upper extremities. The eyes presented the evidences of a double optic neuritis. At the time of operation, February 16th, it was estimated that the loss of weight had been between fifty and sixty pounds. He was practically blind, was wholly unable to sleep, and vomited from ten to twenty times during each twenty-four hours. He was also seen at this time by Drs. Peterson, Bailey, and P. C. Knapp of Boston, all of whom concurred in the diagnosis of cerebellar tumor, probably on the right side near the worm.

On February 16th, under ether anesthesia, a large omega-shaped bone-flap was raised in the right lower occipital region which, when lifted up, broke into the foramen magnum. This exposed the right hemisphere of the cerebellum, which was incised in several places and explored. A small tumor about the size of a hazelnut was found 1¼ inches from the surface near the median line. This was removed in three fragments by means of the finger and a sharp spoon. The lacerated cerebellar tissue was cut away, a drain of sterile gauze introduced, and the wound closed. Twice during the operation it was necessary to infuse a large amount of normal salt solution into the median cephalic vein to prevent col-

[1] During the six months which have now elapsed since the last operation, the patient has had but six convulsions, and is in excellent general health.

lapse. Active stimulation by means of rectal enemas of hot coffee, and strychnin hypodermically was also necessary.

Every untoward symptom ceased after his removal from the table. As soon as the effects of the anesthetic passed off he took and retained food in abundance, his headache disappeared, his eyesight was restored, and he gained rapidly in weight. The wound healed primarily without infection and in a month he was up and about the ward. Two months after the operation he was exhibited at the surgical section of the Academy of Medicine, apparently in perfect health, having gained between forty and fifty pounds in weight. As microscopic examination of the growth showed it to be of a tubercular nature, however, our prognosis was a guarded one.

Shortly after his apparent perfect recovery he became ill, presented evidences of an acute tuberculous process in both lungs, and progressively increasing intracranial pressure. He failed rapidly and died during an attempt to relieve the intracranial pressure by reopening the skull. Autopsy showed an acute miliary tuberculosis of both lungs with local recurrence in the cerebellum.

I desire to refer to one other very interesting condition which may often be relieved by an intracranial operation, and that is *tic-douloureux*, a persistent and progressively increasing trifacial neuralgia. As is well known, the disease frequently resists every method of medical treatment and recurs after division and even excision of the nerve trunks, producing the most intolerable suffering, often resulting in the morphin habit or even suicide. Complete relief in these cases can only be obtained by a removal of the Gasserian ganglion and the intracranial portion of the three nerve trunks by the ingenious operation first suggested to the profession by Hartley.

I have recently operated in a case of this kind, with what at present seems to be a satisfactory result. The patient, a Swede, fifty-six years of age, has complained of pain over the areas supplied by the fifth cranial nerve of the right side for some eight years. At first the attacks of pain occurred at infrequent intervals, and although severe were tolerable. Gradually, however, they became more frequent and severe and so interfered with his work that he became discouraged and, experiencing no relief from the various methods of medicinal treatment, at last became insane and was committed to an asylum. Here, under careful observation and treatment for a number of months he improved somewhat and as his mental symptoms were relieved he was discharged. Shortly afterward the pain became so severe as to be unbearable, and he was admitted to the service of Dr. Joseph Collins at the City Hospital. After careful observation and a thorough test of the strychnin treatment, Dr. Collins made a diagnosis of disease of the ganglion and advised an intracranial operation.

On May 20th, under chloroform anesthesia, an incision was made down to the bone, beginning at the outer angle of the orbit, and extending upward, backward and downward to a point just in front of the tragus of the ear, forming an omega-shaped flap about three inches in diameter. The bone was chiseled through, broken off just above the zygoma, and the flap, composed of skin, temporal muscle and bone turned downward over the cheek. This opened the middle fossa of the skull. The dura was then carefully separated from the base of the skull until the foramen spinosum was reached, and the middle meningeal artery and vein secured and cut off; the dura was then further separated from the bone toward the median line until the foramen rotundum was reached and the second or superior maxillary division of the nerve recognized. The foramen ovale was then found and each division separated from its thin dura sheath, and followed backward to the ganglion, which was then exposed. This dissection required nearly an hour for its accomplishment, owing to the very free hemorrhage which resulted from a slipping of the ligature on the middle meningeal vessels, from the small meningeal artery which could not be secured, owing to its situation at the deepest portion of the wound, and from a large meningeal vein which opened into the cavernous sinus and which was wounded in attempting to remove the dural sheath from one of the divisions of the nerve.

After many experiments in different methods of packing, the second division was raised on a blunt-hook and divided at the entrance of the foramen; the third division had to be divided by the sense of touch as it was found after many attempts to be impossible to keep the blood from the field long enough to permit the procedure to be carried out under the eye. The two free nerve ends were firmly secured in two artery clamps and torn from the first division backward to the ganglion and removed with as much of the ganglion as remained attached to them. The remaining portion of the ganglion was removed by forceps and the sharp spoon. All hemorrhage ceased as soon as the ganglion was removed; the cavity was irrigated with hot salt solution, a small gauze wick introduced, the flap replaced, secured with silkworm-gut sutures, and a sterile gauze dressing applied. As the hemorrhage had been severe the patient was next given 1½ quarts of normal hot salt solution by the median cephalic vein before leaving the table. Practically no reaction followed the operation. His pulse and temperature remained below 100. The wound united by first intention and the patient was up and about the ward

in ten days. The eye was irrigated every day with warm boric acid solution and kept closed under an aseptic gauze dressing for four weeks, after which the patient wore smoked-glass goggles. No inflammatory symptoms appeared in the eye, and the only discomfort complained of by the patient was the numbness of that side of the face and the general physical discomfort following the discontinuance of his morphin. It is now about six weeks since the operation and the man expresses himself as very grateful and entirely free from pain.

Before closing I desire to say a few words in regard to the technic of the operations. When possible the patient's head is shaved two days before the operation, after which the position of the Sylvian and Rolandic fissures are marked out by needle scratches; these, with Reid's base-line give landmarks enabling the operator to locate any of the known cerebral centers, the chief blood-vessels, sinuses, and dural processes. The head is then scrubbed with green soap and hot water for two minutes, and a soap poultice applied for at least four hours. The head is then rescrubbed for ten minutes by the nurse, whose hands have been previously sterilized, a sterilized brush and sterile liquid soap being used after which a wet 1 to 5000 bichlorid-of-mercury dressing is applied. This is removed when the patient is on the operating-table and the wound area rescrubbed for one minute, then douched with alcohol, ether, and sterile water, and surrounded by sterile towels. The operator and all assistants are clothed in sterilized gowns and caps. The assistant administering the anesthetic prepares himself in the same manner as those participating in the operation and during the operation uses a sterile chloroform mask. Sterilized rubber gloves are worn by the operator, his assistants, and the operating-room nurse. When possible the osteoplastic or bone flap operation is performed for the reason that it does not leave a bony defect in the skull.

When the dura is opened the surgeon must remember that he has opened one of the closed serous cavities of the body, and that the danger of infection from any error of technic is as great as in the case of the peritoneum, the pleura, or the synovial sacs, and that an infection here is with great difficulty controlled and leads almost invariably to a fatal result.

If in doubt in regard to the perfection of the technic it is better to drain for twenty-four hours with sterile gauze. Another fact to be remembered is that irrigation of a wound in which the cerebral cortex is exposed with a hot salt solution (115° to 120° F.) has often a marked stimulating effect on the heart.

THE GOVERNMENT SANATORIUM FOR CONSUMPTIVE SOLDIERS OF THE UNITED STATES ARMY.

By EARL S. BULLOCK, M.D.,
ASSISTANT SURGEON U. S. A., STATIONED AT FORT BAYARD, NEW MEXICO.

A SANATORIUM for the treatment of officers and enlisted men of the United States Army, who are suffering from pulmonary tuberculosis, has been recently established by order of the Secretary of War at Fort Bayard, New Mexico. The commanding officer, Major D. M. Appel, Surg. U. S. A., is a man having a special knowledge of tuberculosis, and modern sanatorium methods, and is planning to follow closely the lines of treatment laid down by Dr. E. L. Trudeau at the Saranac Lake Sanatorium.

Although some patients in an advanced stage have been transferred from other military hospitals, so as to avoid the possibility of spreading infection there, yet this sanatorium is designed to meet the needs of those that can be benefited, rather than of hopeless cases. To this end, patients with mixed infection will be carefully separated from pure tuberculous types, and again, convalescents, those free from the bacillus, will be separated from all other patients, and all inmates of the hospital will be obliged to conform to the set of printed rules of which a copy is here given.

INSTRUCTIONS FOR PATIENTS.

Consumption is an infectious disease: it is caused by a germ which is contained in the sputum. For this reason it is necessary that the greatest care be exercised in the disposal of expectoration. Should it be allowed to dry and in the form of dust float around in the air, millions of these germs would be liberated, a grave danger not only to those free from the disease, but also to you, oftentimes undoing in one day the good that has been accomplished by months of care.

Expectorate ONLY in your spitcup, NEVER upon the floor, in the bath-tubs, sinks, or closets, or in your pocket-handkerchiefs. Carry your spitcup with you everywhere, expectorate into it carefully, avoid having to wipe sputum from your lips, whiskers, or from the edges or side of your cup. The only safe method of disposal of sputum is by burning it. Your cups should be burned as soon as half filled and never use one cup for more than twenty-four hours. The metal frames should be washed often with carbolic solution.

Should you, by accident expectorate upon the floor or bedclothes or spill your cup, tell the nurse at once and he will use the necessary disinfectants.

Fresh air and sunlight, rest and good food are necessary. Stay out doors as much as possible, go to bed early, take moderate exercise, eat your meals slowly and masticate your food thoroughly. Do not help yourself to food from dishes with your own fork or spoon; use those provided for that purpose.

Try to refrain from coughing at meal times; with

care you can do much to prevent it. The use of stimulants and of cigarettes is forbidden, smoking and chewing tobacco, in moderation, is permitted when out doors or in the recreation-room.

Whiskers and moustaches, if worn, must be closely trimmed.

PATIENTS NOT BEDRIDDEN WILL OBSERVE THE FOLLOWING RULES:

1. They will occupy their quarters only from 7.30 P.M. until 8 A.M.
2. They must make their own beds and arrange their personal belongings neatly.
3. They must remain outdoors at least eight hours daily.
4. They will not visit in quarters.
5. They will bathe at least once a week.
6. They will not, without special permission, go south of the Administration building.
7. Meals will be served only in the mess-hall.

D. M. APPEL,
Major and Surgeon, U. S. Army,
Commanding Hospital.

Fort Bayard, itself, is a rather old post for New Mexico, dating from 1867, and in view of its abandonment, which has been discussed for some time, it has been permitted to run down, with the exception of absolutely necessary repairs. In consequence but few of the buildings are adapted to the purposes of the sanatorium, and of course, must be replaced by modern structures as soon as possible.

The climate is a subject upon which one might enlarge indefinitely. From the standpoint of physical comfort it is almost ideal and for a sanatorium the climate as well as the location can hardly be excelled.

Fort Bayard lies in a sheltered valley—from it one can plainly see the mountains of old Mexico, more than sixty miles away. They are a never changing hazy blue, only a shade deeper than the sky, which day after day is the same cloudless blue. The perfect clearness of the atmosphere is accompanied by the frequent phenomena of mirage. Down the valley, and a few miles from the post, the plain is apparently dotted with lakes of all shapes and sizes, but the carcasses of cattle dead for lack of water prove that Nature is simply painting pictures on the horizon.

Looking east, and about five miles away, one sees the low, rocky Santa Rita mountains, the cliffs of which were carved and chisled by the hand of man centuries ago. The most prominent landmark of the range is the Kneeling Nun of Santa Rita, a rock visible for miles in nearly all directions, representing the figure of a nun kneeling before a cliff which serves as an altar. Toward the west and about sixteen miles distant are the mountains at the foot of which lies Silver City, while to the north there is still another range. These mountainous surroundings shelter Fort Bayard in part, at least, from the fierce winds which are prevalent during the spring months and constitute the only climatic drawbacks. These winds sweep from ocean to ocean at this latitude, and raise the sand and dust so that sometimes it is not possible to see a building twenty feet away. Such storms are, of course, exceedingly irritating, but fortunately they only prevail for a short time.

At Albuquerque they occasionally use snow shovels to remove the sand and dust from the walks after an unusually severe storm. So it can be readily appreciated why Fort Bayard is proud of its sheltered situation, though even here, to be more honest than is common in the writer of climatic articles, the dust storms are bad enough.

Vegetation is scant, were it otherwise different conditions would prevail and the consumptives would be obliged to seek another Mecca. What little growth there is has a stunted, burned up, very thirsty appearance. There is a characteristic desert flora and fauna, though by all odds geology is the science that most abounds, particularly that branch which deals with volcanic rocks. Fort Bayard is too high, and therefore almost too cold, for the comfort of those destructive reptiles of New Mexico, rattlesnakes, tarantulas, scorpions, centipedes, and Gila monsters. While they are not wholly absent, they are not very abundant. The three elements latitude, altitude, and humidity in combination, make the climate what it is and contributes to the climate a very high sun temperature in summer and a relatively high sun temperature in winter. From this comes the saying that its always warm in the sun.

The altitude, 6040 feet, causes rapid evaporation and at this height constant motion of the air is a feature of the climate. The altitude, consequently, modifies the sun's heat at all seasons, shortens the growing seasons and lengthens the winter. The great dryness of this region, more than all other elements combined, determine the peculiar climatic features. It aids the altitude in still further increasing the rapidity of evaporation, and then to make a very hot day apparently cool. As dry air has a very limited capacity for retaining heat the result is a great and sudden drop of temperature as soon as the sun goes down or upon going from sunshine to shade. The practical application is, of course, that one can always be cool in summer by remaining in the shade, warm in winter by staying in the sun. This explains why one must always sleep under blankets even in August. At Christmas time it is common to see men working out of doors without coats or vests when in the sun, but it is almost

comical to see the rush for outer garments when the sun begins to go down. Again, the evaporation is so very rapid that visible perspiration is uncommon except upon really violent exertion. Even during the rainy season it seldom rains, the total rainfall being less than 15 inches a year.

The dryness is further impressed upon the visitors to southern New Mexico by the the temptation to moisten the lips—which, if persisted in, causes them to become cracked and sore.

From a sanatorium point of view the advantages of the climate are briefly as follows:

Sufficient altitude to act as a general, and, especially, as a blood, tonic, vastly increasing the number of red corpuscles and amount of hemoglobin.

The dryness not only aids altitude in providing a relatively aseptic atmosphere, but it has in itself a distinctly beneficial effect in pulmonary tuberculosis which, though empiric, is none the less well established

The small rainfall and cloudless skies permit daily life in the open air which is *per se* the most important *desideratum* in the management.

Climatologic therapeutics has not yet reached an epoch which makes it possible to successfully select the particular climates, altitudes, etc., that will give the maximum benefit to any patient. Only trial will demonstrate the individual's adaptibility to a climate.

All sorts of patients may do well in all sorts of climates, meaning, of course, slight variations due to differences in altitude and local influences of practically the same general climate (Eastern Colorado, New Mexico, Arizona, and Northwestern Texas). On the other hand all sorts of cases may do badly in all sorts of climates.

The question of suitable altitude is very simple. Patients with advanced disease should begin at a low altitude and ascend gradually, particularly if there is present a hemorrhagic tendency, arteriosclerosis, or heart complications. But as high altitude is a therapuetic agent in pulmonary tuberculosis whether, complicated by sepsis or not, patients should continue to ascend up to 6000 or 7000 feet as long as they feel comfortable; and when there is not sufficient lung surface for adequate aeration of the blood Nature herself will call a halt.

Patients in advanced stages of the disease on first arriving here generally have suffered, in addition to exhaustion, from dyspnea but without exception they soon began to feel better than they did in the East, the only difference being that there they were in the habit of getting about more, while here they were content to sit on the verandas all day, and retire with the sun. The danger supposed to threaten patients advanced in the disease at such a high altitude, was not apparent, neither has it been observed that the effect of tea, coffee, and tobacco was deleterious to those that indulged, in spite of the opinion to the contrary of some who advocate lower altitudes.

In regard to the relative differences between Colorado, Northwestern Texas, New Mexico, and Arizona, where the altitude and latitude are equal, the climate of the last three is practically the same. Colorado is relatively dry, as is well-known, but wet compared with the others. It is also much colder and subject to greater extremes of temperature, Colorado is much the best place for the poor "lunger" because necessities are cheaper and the chances of getting suitable employment are better. The wealthy patient can get what he requires almost anywhere. In Mexico and Arizona an invalid cannot live comfortably for less than $3.00 per day.

Those in a position to form an unbiased opinion agree that portions of New Mexico and Arizona furnish the ideal climatic environment for consumptives. And from this point of view Colorado occupies an entirely secondary position. But, on the other hand, luxuries and comforts, as well as congenial society are found almost everywhere in Colorado. While further south the necessities, to say nothing of the luxuries of invalidism, are beyond the reach of the poor man. Colorado with its wonderful climate is good, but the desert of the Southwest is better from a climatic point of view, and when it becomes the recognized sanatorium of the United States, as it is bound to do in a short time, many of the drawbacks and discomforts will be eliminated.

In a high altitude secretion and excretion are all augmented, metabolism in general becomes a more perfect part of life's mechanism. The dyspeptic, the neurasthenic, the rheumatic, the consumptive, the gouty, are nearly all benefited. Therefore, a high altitude, not 2000 feet—but 5000 to 7000 feet or just as high as a patient can live in comfortably, is to be generally recommended.

A word as to transportation: nearly all the places frequented by invalids in the Southwest are on the great continental trunk lines (Santa Fé and Southern Pacific). The majority are on the Santa Fé where the passenger accommodations are very excellent.

The Harvey Restaurants are the salvation of many a poor lunger in this country. One thing, however, must be remembered: the prices, though reasonable enough considering the distance everything must come, are, in fact, strictly on the Delmonico scale.

All medical men appreciate the importance of a proper mental state on the part of the patient in aid-

ing recovery from any disease, and so it may be said positively that if a consumptive must come West to worry and be homesick he would better remain at home. There is no country on earth, with the possible exception of the North Pole, that can compete with the great Southwest for endemic nostalgia. If worry be added to homesickness the case is hopeless. Therefore, the immigration of the wife and family with the invalid husband and father or the mother with the invalid son or daughters is a potent factor in recovery, for mental peace and hopefulness are fully as important as a suitable climate for the recovery of tuberculosis patients.

EMPYEMA IN INFANTS.

BY DAVID BOVAIRD, JR., M.D.,
OF NEW YORK;
PATHOLOGIST TO THE NEW YORK FOUNDLING HOSPITAL; ASSISTANT TO CHAIR OF PEDIATRICS, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

EMPYEMA in children is a familiar topic, but if we consult the reports or articles upon this subject we find that few of the cases occur in children less than three years of age, while those belonging to the age of infancy (under two years) are rarer still. It is the desire of the writer to direct attention to the frequency of the occurrence of empyema during the first two years of life, and to certain of the clinical features that belong to the disease during that period.

In the pathological records of the New York Foundling Hospital in the last ten years we find a total of 82 cases of empyema. Of these, 69 were under two years of age, only 13 were beyond that age. These figures may serve to indicate the gravity of this affection during the earlier period. Of these 69 cases, 42 occurred in boys, and 27 in girls. As to the distribution, the right side was involved in 28 patients, the left in 24, both sides in 17. The frequency of this involvement of both sides serves, in part, to account for the high mortality. Furthermore, we find that in one case there was a complicating meningitis, in another an acute peritonitis, while in six cases acute pericarditis had helped to produce a fatal termination. Finally, in forty-one cases there was more or less pneumonia present. The character of the pulmonary involvement varied considerably, some of the cases showed a diffuse pneumonia involving one or more lobes; others only scattered areas of broad pneumonia, while in a third class the consolidation was found only in the superficial portion of the lung which was in contact with the purulent effusion. In the first two classes it is generally agreed that the empyema is secondary to the pulmonary affection, while in the last class it is an open question. Attention would be particularly called to the fact that we have still left a total of twenty eight patients in which there was not any involvement of the lungs found. Objection may be urged that it would not be safe to conclude that because pneumonia was not found at autopsy there had not been any during life. Such objection would certainly hold good for the cases seen in children of greater age or in adults, since in such cases weeks may intervene between the onset of pulmonary symptoms and the discovery of empyema, but in infants the clinical course is so short that doubtless the conditions found at autopsy quite fairly represent the conditions during life. Special attention is directed to this point because it is generally accepted that pneumonia of some form is regularly the precursor of empyema in children.

The records show that in 1 case the empyema was secondary to a general tuberculosis, in 1 to pertussis, in 1 to gangrenous dermatitis, in 2 to enterocolitis, in 2 to diphtheria, in 2 to erysipelas, and in 5 to measles. The data on this point are not complete, and this summary is given for the sake of indicating the variety of the diseases in which empyema may occur as a complication. The absence of scarlet fever from our list is probably accounted for by the rarity of this disease among infants

There is one form of empyema which is, in our experience, peculiar to the early years of life. Sometimes it is designated in the records as pleuropneumonia, sometimes empyema, the designation apparently depending upon the stage of the disease met with at autopsy. In the early cases we find one or more lobes of one or both lungs presenting a fairly typical lobar consolidation, while the pleura overlying the affected lung is thickened, whitish in color, more or less opaque, and coated with a greenish-white or yellow exudate sometimes measuring half an inch in thickness. Usually the parietal pleura is similarly thickened. The pleural cavity may contain only a dram or two of clear serum. Under the microscope the pleural exudate is seen to consist of fibrin and pus. At a later stage the pleural exudate is found in a state of disintegration, and the fluid present in the pleural cavity is thin pus. It is not uncommon to find the pleural contents so thick that they will not flow, but they can be readily scooped out in great masses. It is this type of the affection that is likely to be complicated by pericarditis, meningitis, or peritonitis.

In the majority of cases the purulent effusion is found in the posterior and lower portion of the pleura, but in some of the cases it was noted that the pus was sacculated anteriorly even at the apex of the lung. In whatever situation the pus is found

it is not uncommon for the effusion to be so shut in by adhesions that changes in the position of the body would have little or no influence upon the level of the fluid.

The character of the fluid found varies greatly. Sometimes it is thin and watery; much more often it is thick and creamy. The color is red, reddish-brown, green, greenish-yellow, or yellow. It is, of course, turbid or opaque, and under the microscope shows pus-cells. In none of our cases was it foul-smelling.

The clinical features of empyema in infants are quite as interesting as the pathological findings. In the Foundling Hospital it is generally admitted that there is no disease in which error in diagnosis is so frequently made, the error consisting in failure to suspect and to demonstrate the presence of pus in the pleural cavity. Hardly an interne passes through his year's service without scoring one or more such failures. One frank graduate recently said that just as he was about to leave the hospital at the very conclusion of his service he went to see an autopsy upon a case which he had followed for four days without a doubt that it was pneumonia, only to find a chest full of pus! The explanation of these failures lies partly in the difficulty of diagnosis of any pulmonary condition in an infant. The small size of the chest, the close relation of the lung on one side to the solid liver, on the other to the hollow stomach; the difficulty of securing a quiet examination, the inability to secure the assistance of the patient in the study of the voice and breathing all serve to lesson the information we may gain from physical examination and obscure the interpretation of its results. The frequent presence of pneumonia with empyema likewise adds difficulty to the situation.

But, finally, it seems that the chief cause of our errors is that we come to the study of these cases with the clinical picture of empyema as it occurs in adults so fixed in our minds that we cannot break away from it. We think of empyema as an affection that develops, as a rule, only after a definite pneumonia and in the course of several weeks. We expect to have time to study the case, note the character of the temperature, the occurrence of profuse perspiration, etc., and, if fluid is present, to watch its gradual rise. We have to learn that the clinical course of empyema in infants is short and critical. Our records show that some of the cases die within forty-eight hours after invasion; that the greater number of these sixty-nine cases have proved fatal within a week; that few of them have lived longer than two weeks. We may fairly say that in empyema in infants we have to do with days, where we have weeks or months in the case of adults.

Moreover, the rational signs of empyema in infants are inseparable from those of pneumonia. This holds true whether or not pneumonia precedes or accompanies the development of empyema. We have the same fever, restlessness, rapid pulse, and respiration; the same dilatation of the alæ nasi, cough, and perhaps the expiratory grunt upon which emphasis is often laid in the diagnosis of pneumonia. In short, rational signs are of no help in the matter of differential diagnosis.

Physical signs are of little more assistance. Inspection in an infant will only show an immobility of the affected side common to both pneumonia and empyema. Percussion, if it gives flatness over any part of the lung, should lead us to suspect fluid, but cannot demonstrate its presence. Diminution of the voice and breathing sounds should confirm the suspicion. Bronchial voice and breathing are often heard over pleural effusions in infants, but if so they are usually of a distinct character that is at least suggestive. Palpation may give absence of vocal fremitus, but this is difficult of determination on the small thorax. Displacement of the heart is a reliable sign if it can be demonstrated. It is naturally most likely to be found with left sided effusions, but at the age of which we are speaking it is rarely of decisive help. The physical signs have been gone over in this way only to give point to the repetition of the fact that no one sign or set of signs can be relied upon to settle the question. Marked dulness or flatness over any part of the lung, particularly if it be associated with diminution of the voice and breathing sounds or displacement of the heart, should suggest fluid, and call for the use of the exploring needle.

In view of what has been said on the character of the effusion in these cases, the absurdity of using a hypodermic needle for exploration is apparent. A large needle is a necessity. One approaching the size of the lead in a lead pencil is best. A needle about an inch and a half in length can be handled with much more ease and certainty than the long ones so much in vogue. Such a length is quite sufficient to penetrate the thorax of a child and reach pus if present. The terms fluid and pus have been used interchangeably simply because if fluid is present in these cases it is almost always pus. In the class of cases referred to as sometimes called pleuropneumonia we may draw off a clear serum. A day or two later the same case will show pus. The site of the exploratory puncture is determined by the situation of the dulness or flatness. If necessary, the puncture should be repeated in several places and on

successive days. In the early stages of a thick purulent exudate no aspirating needle would show the character of the effusion.

Once pus is found there is a clear indication for drainage. The removal of the pus by aspiration is sometimes resorted to for temporary relief, but this procedure cannot be relied upon as a method of treatment. Permanent drainage must be established. In infants this is satisfactorily accomplished by making a simple incision in an intercostal space, and inserting two drainage-tubes side by side as large as the space will admit. The site of the incision must be determined by the site of the effusion. Our autopsies show that incisions either located behind and and below the angle of the scapula or in the axilla, either anteriorily or posteriorly, drain the pleural cavity thoroughly. The time for the removal of the tubes must be determined by the subsidence of the discharge. In infants it is possible to remove the tubes much earlier than in adults. The tubes must be secured from slipping into the cavity of the pleura by passing a safety-pin through the outer edge. They should be covered by an abundant dressing of sterile gauze and cotton.

In cases that progress favorably there is usually no difficulty in the expansion of the lung. Apart from drainage the treatment must be simply aimed to support the strength of the child. To summarize the points it is desired to emphasize:

1. Empyema is not uncommon in the first two years of life, and even in the early months. Of the 69 fatal cases on our records 11 occurred in children under six months of age, 40 occurred in children between six months and one year, and 18 occurred in children between one and two years. The youngest patient was two months and nineteen days old.

2. The mortality during this period is very high.

3. Empyema in infants is very frequently mistaken for pneumonia.

4. The rational signs are the same as those of pneumonia in children.

5. The physical signs cannot be relied upon for diagnosis.

6. Exploration is called for in every case in which, with the rational signs of pulmonary disease, we find marked dulness or flatness over any part of the lung, especially if accompanied by diminution or absence of voice and breathing or displacement of the heart.

7. That exploration should be made with a large needle and repeated if necessary. None of our cases has ever shown harm from the use of the needle: many have been missed by reason of failure to use it.

8. Practically all pleural effiusions in infancy are either purulent from the beginning or soon become so.

9. When pus is found drainage is called for. Incision in an intercostal space with the insertion of drainage tubes answers this end thoroughly.

126 WEST FIFTY-EIGHTH STREET.

CLINICAL LECTURE.

SURGICAL CLINIC OF PROFESSOR SENN.[1]

CASE I. *Sarcoma of the Nasopharyngeal Space.*—Mr. W., aged forty-three. No venereal history. Nine months previously he was supposed to have caught a cold in the head. He suffered from difficult breathing due to stenosis of the right nostril. Four months ago he could only breathe through the mouth as there was complete nasal occlusion. At this time a large swelling was noticed in the nasopharyngeal space. There was marked dysphagia. The recumbent position caused a sensation of cerebral congestion. Two months later portions of a tumor were removed through the nose, which greatly aggravated the existing conditions.

Operation.—Preliminary ligation of right common carotid artery was performed because the disease was more extensive on that side. An incision four inches in length along the anterior border of the sternocleidomastoid muscle was made extending through the skin and superficial fascia; then blunt dissection until the sheath was reached, which was opened widely, freely exposing its contents; thus obviating the possibility of including important contiguous structures in the ligature. After introducing double ligatures of catgut, traction was made on the artery by means of the ligatures as a secondary pracaution in liberating the artery. Following this they were tied a quarter of an inch apart. The patient who had been fully anesthetized was now allowed to become semi-conscious. A guy rope of silk was next passed through the tip of the tongue. The soft palate was divided into two lateral halves by means of the broad blade of the Paquelin cautery, thus exposing the tumor mass which was removed piece-meal, largely with the use of blunt instruments. Profuse hemorrhage, which in spite of precautions, caused the patient to become asphyxiated several times, necessitated a delay in the operation until the patient revived. The tumor extended far back to the base of the skull. The soft palate was excised with scissors and the bed of the tumor was thoroughly cauterized. The nasal fossa and the nasopharyngeal spaces were lightly tamponed with iodoform gauze. One week later all the symptoms of difficult breathing, pain, and cerebral congestion had disappeared.

CASE II. *Recurrent Carcinoma of Tongue.*—Mr. S., aged fifty. Prussian, married. The patient had been an inveterate smoker for years. Three years previously a fissure appeared on the upper surface of the tongue near its tip, which, five months ago was subjected to partial excision. Three months later there was a reappearance

[1] Held at Rush Medical College, Chicago, Tuesday November 28, 1899. Reported by Emanuel J. Senn, M.D., Associate in Surgery, Rush Medical College.

of the disease in the old scar with greatly enlarged lymphatics,

Operation.—Partial anesthesia. A semilunar incision on right side of neck with convexity downward extending from the symphysis mentis to the mastoid process was made which was joined by an incision extending downward along the anterior border of the sternocleidomastoid muscle. An enlarged gland behind the sternocleidomastoid muscle and a chain of glands around the great vessels of the neck were removed. Later the mouth was opened according to Kocher's method and by careful dissection one-half of the floor of the mouth was removed *en masse*, with some enlarged submental glands. The tongue, by means of a silk loop passed through the tip was brought through the opening in the floor of the mouth and was amputated at its base. The cut lingual arteries were promptly caught and ligated. The two flaps at the base of the tongue were sutured with catgut, the large wound packed with gauze, and the skin-flap sutured in position; tubular drainage. The stump of the tongue was transfixed with a silk ligature, which was brought through the mouth and fastened to a support which was incorporated in a plaster-of-Paris cap, in order to guard against falling backward of the stump. One week later the patient was in excellent condition; in spite of the absence of the tongue, he was able to articulate, and could talk almost as well as before the operation.

CASE III. *Pyonephrosis and Nephrolithiasis.*—Mrs. S., twenty-seven years of age, married five years. Four years previously, at birth of first child, she was repeatedly catheterized. Pain in bladder and right renal region followed and she experienced a sensation as if an object were in the kidney attempting to escape. Two years ago nephrectomy was performed and a calculus is said to have been removed. The fistula closed seven weeks later but no improvement was noticed after the operation, and the patient had renal colic at repeated intervals.

Operation.—Simon's incision, extending from the twelfth rib to the crest of the ilium was made. The capsule of the kidney was found adherent by reason of the previous operation. The kidney was hard and did not give any sense of fluctuation. Exploratory puncture revealed urine heavily loaded with pus. The needle of the syringe was left *in situ* to use as a guide. Pelvis of kidney was opened by means of Paquelin cautery. Digital exploration of the pelvis and calices. In the deep portion of the wound, the finger came in contact with a soft stone embedded in a calyx near the uretal orifice. This could not be removed entire on account of its location and its fragility. Its removal was with difficulty effected by means of a dull curette. The wound was irrigated and the renal wound enlarged by means of the cautery, nearly dividing the kidney in two halves. This secured requisite drainage and free exposure of all the calices. Drainage was made by means of three large rubber tubes.

CASE IV. *Traumatic Epiphyseolysis of the Femur.*—Annie, aged thirteen. Eleven weeks before, the patient fell from a height, sustaining an injury in the neighborhood of the knee-joint. This had been previously diagnosed as a fracture or dislocation. There was shortening of the leg two and a half inches, with projection of lower fragment in an outward and backward direction. Paralysis of limb below the seat of injury was present and a radiograph showed a large callus in connection with lower fragment. An incision on the outer aspect of the limb in a line with the intermuscular septum revealed an epiphyseolysis of the lower extremity of the femur. Traction was of no avail in the mobilization of the lower fragment and was attended by considerable hemorrhage. A disk of bone was removed by the saw from the upper fragment, after which the two fragments could be brought in coaptation. Suturing of wound, drainage, and large dressing, plaster of Paris, and fenestrated fixation splint completed the operation. Four hours after operation the temperature reached 104° F. This continued with some variation for two days when the dressing was changed and a considerable amount of bloody serum escaped, after which the temperature returned in a few hours to nearly normal.

CASE V. *Backward Dislocation of Elbow-joint.*—Mr. W., young adult. The injury occurred five weeks previously. There was swelling of elbow-joint and the arm was in extension which could not be overcome. Marked prominence of olecranon process was present. The diagnosis of backward dislocation was confirmed by skiagraph. The patient was placed under the influence of ether and a bloodless reduction was made by careful forced flexion of the forearm, extension and counter extension. Traction was made by means of a bandage passed around the elbow with a clove hitch at the wrist. Through slight manipulation reduction was readily made, not, however, without causing a fracture of the tip of the olecranon.

CASE VI. *Tuberculosis of the Metatarsophalangeal Joint of the Little Toe.*—Mrs. V., aged thirty-one. One sister died from phthisis. Six months previously the patient had tuberculous peritonitis which subsided after one tapping and injection of iodoform glycerin emulsion. One year ago a fluctuating abscess appeared on the outer side of the little toe. This was tapped and injected with iodoform emulsion. As a fistulous opening appeared, which persisted to the present time, amputation of the entire toe and metatarsal bone except its proximal head was performed.

CASE VII. *Epithelioma of the Lower Lip.*—Mr. S., aged fifty-one. The disease began as a papule on the lower lip three months previously, situated slightly to the middle line. Later an ulcer about the size of a dime developed. The submental glands were not enlarged. Operation was done without an anesthetic a V-shaped incision being made. Hemorrhage was controlled by digital compression. The apex of the incision was carried down to the lower border of the jaw in order to prevent both the possibility of leaving diseased lymphatics and to secure a more gradual convergence of the margins of the wound whereby a more perfect cosmetic result is secured. The incision in the mucous membrane of the mouth was sutured separately with catgut. The external wound was closed with a few silkworm tension sutures and with horsehair coaptation sutures. The external wound was

sealed with collodion iodoform gauze and was then covered with cotton.

CLINICAL MEMORANDUM.

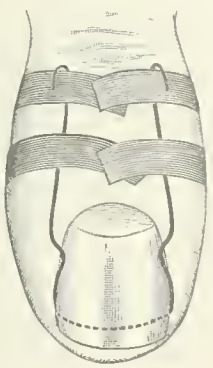
A SIMPLE METHOD FOR THE TREATMENT OF INGROWING NAILS.—A CLINICAL SUGGESTION.

BY GERALD B. WEBB, M.D.,
OF COLORADO SPRINGS, COL.

HAVING tried all methods of treatment, and having been obliged at times to resort to partial excision under cocain, I one day had to treat an obstinate case of ingrowing finger-nails due to improper manicuring. It then struck me that there should be some method of cure, especially for stubborn cases, that would leave no deformity, and I hit on the idea of using silver wire, as represented in the diagram.

For toe-nails I have used it about the thickness of an ordinary pin. The wire should be annealed, and carefully bent to fit the under free surface of the nail, catching and lifting up the lateral edges as far back as the cuticle. Artery forceps will serve as pliers. The ends are carried along the dorsum of the toe and strapped down to the skin with surgical plaster. A pledget of cotton should be twisted around the points which have previously been bent away from the skin. By this means the

FIG. 1.



Illustrating Method of Treatment.

jagged edge of nail is replaced by the smooth, round, non-irritating surface of the wire, and even cases with pus quickly subside. The patient suffers no discomfort if the wire is properly molded, being able to go around as usual with his boot on, and if supplied with adhesive plaster can reapply the wire and cleanse the toe at his pleasure. The only disadvantage is the necessity of wearing the appliance until the toe-nail grows out properly, but this is unquestionably better than the sacrifice of part of the nail and subsequent deformity.

MEDICAL PROGRESS.

On the Etiology and Pathology of the Kedani Disease.—In 1892 Dr. K. Tanaka of Japan made his first observations on a peculiar malady found in that country, and which thus far has not been recognized as occurring anywhere else. In the (*Centralblatt f. Bakteriologie*, 26, p.437, October 28, 1899,) he makes some further contributions to a knowledge of this interesting disease. It is typically one of the group of the exanthemata. The attack usually comes on without premonitory symptoms with a chill and abrupt rise in temperature. The pulse is accelerated and the respiratory activity increased. In a few days the patient is severely ill. Nervous symptoms develop in a short time. On the third to seventh day the eruption occurs. It is urticarious in its general type. Swelling of the lymph-nodes occurs, the face is reddened and turgid, and the conjunctivæ markedly congested. The tongue dries rapidly, and the lungs are the seat of an active bronchitis. The spleen is increased in size. There is gradually developing anorexia and constipation. The kidneys show the lesions of an acute exudative nephritis or acute degeneration. In from ten to thirteen days death usually occurs in from forty to seventy per cent. of those affected.

The author describes a minute moth that is widely spread in the region where this disease is endemic. This moth makes a small punctured wound in the skin when it bites, which is its habit, and it is from this mode of infection that the disease originates. Tanaka believes that he has found a bacillus, a proteus, resembling the Proteus Hauseri, which is the true agent of infection. Careful search was made for some form of plasmodium as the analogy of the method of infection were so marked with that produced by the mosquito, but no such animal blood-parasite was found. A detailed description of the biological characters of the bacteruim is given with illustrations.

Analgesia of the Ulnar Nerve in Epilepsy.—LANNOIS and CARRIER(*Revue de Med.*, November, 1899) contribute a clinical study on a recently observed phenomenon, *i.e.*, analgesia of the ulnar nerve (Biernacki's sign) in the epitrochlear space, between the internal condyle of the humerus and the olecranon. As is known to all, its pressure, a classical method of rousing inebriates, is attended with sharp radiating pains accompanied by tingling of the hands and fingers. Analgesia to pressure on this nerve has been observed as a comparatively common symptom in general paresis, and also rarely in locomotor ataxia, and Biernacki has made an extended series of observations on this phenomenon. In the present inquiry Lannois and Carrier have filled out the series of investigations of Hildenberg, who found that seventy-five per cent. of 79 general paralytics showed this phenomenon. This high percentage, however, they attribute to the fact that there were 13 epileptics included, 12 of whom gave this symptom. In their studies 130 epileptics are reported on including 80 females and 50 males. Of the 80 females 40, fifty per cent., showed normal ulnar-nerve symptoms on both sides. In 11 cases, twenty-three per cent., there was diminished sensibility on both sides. Normal sensibility of one side only was present in 9 cases, while there was complete analgesia on both sides in 14 cases, and complete analgesia on one side in 10 cases. Thus there were fifty-five per cent. normal nerves,

twenty per cent. with diminished sensibility, and twenty four per cent. with complete analgesia. In 50 male epileptics fifty-eight per cent. showed normal sensibility, twenty-eight per cent. diminished sensibility, and fourteen per cent. were analgesic. The combined figures show 56.5 per cent. normal nerves; 23.4 per cent. diminished sensibility, and twenty per cent. showed the positive Biernacki sign. These figures are much lower than the figures of Hildenberg and Foebel, and Lannois and Carrier refuse to acknowledge this symptom as one of the stigmata of epilepsy. As a helpful sign in the diagnosis of hysteria from epilepsy, however, they believe that it may have some value. It is caused, they believe, in the post-epileptic interval by the bruising of the nerve consequent to the attack.

Treatment of Acute Psychoses by Rest in Bed.—SERIEUX and FARNANIER (*Semaine Med.*, October 11, 1899) speak highly of the good which often follows the treatment of acute cerebral disorders by rest in bed. It is usually possible to persuade insane patients that on account of their fever, or as an aid to digestion, or for some other reason, it is desirable that they remain in bed. A nurse is, of course, necessary, and it is of advantage to have the room attractive. The exact physiological action of a horizontal position is not known. Certain it is that it reduces the rate of the pulse and respiration, and by slightly reducing the blood-pressure it lowers the central temperature, diminishes the destruction of the red blood-cells, and increases the weight of the body. There follows as the result of this method of treatment a lessening of the excitement and an improvement of the patient's general condition. The treatment should be supplemented by such therapeutic measures, medicinal or otherwise, as may be indicated, including massage, electricity, hydrotherapy, etc. The mental states most suitable to this form of treatment are acute febrile delirium, alcoholic delirium, morphinomania, mental confusion, delirium, alcoholic delirium of hysteria or epilepsy, and acute mania and melancholia. In chronic mental disorders rest in bed is not advisable.

Diarrhea Occurring in Tuberculosis. — PLICQUE (*La Presse Médicale*, October 7, 1899) says that diarrhea occurring in connection with tuberculosis may be due simply to an excess of fat. This often occurs in patients who suffer from tuberculosis of the joints. It may also be due to treatment by drugs, or it may be the result, most serious of all, of intestinal ulcerations. In the last stages of phthisis such is frequently the case. The diarrhea under these circumstances is usually followed by death. The only justifiable treatment of diarrhea of this type is to relieve the patient with morphin and to prevent severe colic by irrigation of the intestine with injections containing a little laudanum. Diarrhea from other causes has a greater therapeutic interest. A common mistake in treatment is to add too much fat to the diet. Saponification not taking place, unchanged fat passes through the intestines and induces a diarrhea. Under such circumstances the amount of ingested fat, whether cod-liver oil, olive oil, or even butter, should be somewhat limited. Even the yolks of eggs are sometimes injurious to a patient in this condition. Milk can usually be taken without ill effect. In every case the patient should take a long rest after eating, and should drink some hot fluid with meals, such as tea, hot wine, hot milk, etc. Another cause for diarrhea, often seen in young women, is the swallowing of the sputa. The amount of medicine ingested should be reduced to the minimum. Arsenic, the sulphates, and atropin should not be given. The phosphate of chalk and tannin may be taken with advantage. When creosote is not tolerated by the mouth it should be given by the rectum, 30 or 40 minims being mixed with an ounce of almond oil and the yolk of an egg, and shaken into a very fine emulsion with 6 ounces of water. If necessary a little gum arabic may be added to perfect the emulsion. This mixture is best injected after the patient has retired at night. Similar measures should be tried even if tuberculous enteritis is present, but the improvement will be slight under such circumstances. The presence of blood in the stools even in small quantities makes the prognosis very grave.

Appendicitis.—GILBERT BARLING (*Edinburgh Med. Journal*, December, 1899) contributes the results of operation in 117 cases, with some considerations on the questions of diagnosis, of recurrence, and of mortality. Of this number of cases 42 were operated on in a quiet interval. Of these 1 died. The remaining 75 cases he divides into four groups.

1. The "safe" abscess, in which the pus is localized by adhesions from the general peritoneal cavity, and the abscess is adherent to some part of the anterior parietal peritoneum, so that the surgeon opens directly into the pus without risk of infecting the general abdominal cavity.

2. The "non-adherent" abscess, in which the pus is shut off by adhesion from the general cavity, but the abscess is not adherent to the anterior parietal peritoneum, and the operator has to open the general cavity to seek the pus and evacuate it, and so runs the risk of general peritoneal infection.

3. The "subacute" widespread suppurative peritonitis, which approximates the next class, though there is considerable tendency for the inflammation to be limited by adhesion, and the peritoneum above the line of the transverse colon generally escapes.

4. The acute fulminating peritonitis, due to perforation or gangrene of the vermiform appendix, before limiting adhesions of any degree have formed.

The results of operation show that of Group 1, the "safe" abscess, but one case in nineteen operated on died, In none of these cases was the appendix removed. Up to the present time but one recurrence had occurred.

In Group 2, "non-adherent abscess," there were twenty-two cases, all of which recovered. In thirteen the appendix was not removed.

In Group 3 nine cases occurred with three deaths. In only one of these cases was the appendix removed.

In Group 4 there were twenty-six cases, showing fifteen recoveries and eleven deaths.

In addition to the author's statistics the paper contains little that is noteworthy or new.

CORONERS' DUTIES—PHYSICIANS' REPUTATIONS.

THE authentic account of a recent flagrant abuse of the authority of the Coroner of New York City is briefly given in our report of the last meeting of the New York County Medical Society. Two physicians were asked by patients of theirs to see a poor sufferer unable to pay for medical attendance. They did so at an interval of two weeks from one another, the second recommending her removal to Bellevue Hospital. The case terminated fatally at the hospital. A coroner's physician decided, on what cannot but seem extremely inadequate grounds, that death had resulted from criminal abortion. Both the medical attendants were arrested and imprisoned. Slight additional investigation showed the utter baselessness of the charge, and the physicians were cleared of all blame in the case.

Of course by this time the harm had been done. For an act of charity physicians had been subjected to the indignity of arrest and imprisonment, to days of worry and injured feeling, and, though completely exonerated by the authorities, their professional reputations were seriously endangered by the unenviable notoriety given to the parties by the press. For it all there is, it seems, absolutely no legal redress. No one is responsible before the law for the mistake. This is, of course, an extremely serious state of affairs. Already there are many physicians who hesitate about the fulfilment of their duty in certain cases because of the liability to involvement in suspicious circumstances. If previous good standing in the profession will not serve to protect physicians from such groundless accusations, then every physician will hesitate to have anything to do with cases that above all others often need prompt and efficient attention. The subject has been placed in the hands of the *comitia minora* of the New York County Medical Society for investigation and for a report as to the advisability of a legislative remedy for present abuses. We sincerely hope that it will receive the most thorough consideration and that some efficient means of relief may be suggested. In Massachusetts they have done away with the office of coroner altogether and do not appear to regret his going. Certainly here in New York his official actions may be so hedged about by safeguards that his powers cannot be used to injure honorable professional men. There is enough crime, flagrant, almost open crime, to occupy the attention of the office in just the lines of this case without the necessity for arrests on slight suspicions. The standing of a medical man in his profession must be the first consideration in such cases. If that is high, then circumstantial evidence, unless of the most conclusive character, must not be permitted to lead to official steps that shall peril his reputation.

THE MEDICAL CORPS OF THE ARMY.

A BILL for the numerical increase of the Army Medical Corps and for the furtherance of its efficiency has recently been prepared by Surgeon-General Sternberg and will be submitted by him to the coming Congress for legislative action. While even in time of peace, with an army of 25,000 men the number of medical officers was repeatedly reported as being insufficient for the needs of the service, the recent increase of the standing forces to 62,000 men, the establishment in the United States of twenty-eight garrisoned sea-coast defences, the forty-two independent commands now serving in Cuba, Porto Rico and Hawaii, together with the

large number of troups in the Philippine Islands, all combine to render the present strength of the Medical Department pitifully inadequate. It will be remembered that last winter, when Congress authorized a large increase in the combatant forces, no provision whatever was made for a proportionate increase of medical officers. As a consequence, further recourse to the wholly unsatisfactory system of employing civilian physicians under contract has been necessary, and at present not one third of the medical men serving under the colors are trained medical officers. The present authorized strength of the Medical Corps is 192 and General Sternberg asks for an increase of 124 medical officers; an addition which must be considered as extremely moderate in view of the fact that the strength of the army—for the health and care of which the Medical Department is responsible—has been increased two and one half times.

The work of the army medical officer is largely specialized and it will not do to entertain the idea that the civilian practitioner, however well qualified he may be in the practice of his profession, is at once competent to perform the multifarious duties connected with the medical service of the military establishment. Surgery is limited in the army, the practice of medicine is circumscribed within narrow limits and the army surgeon is, under regulations, primarily a sanitary officer. Hygiene, however, is a branch of medical science which, being unremunerative furnishes no financial stimulus for its study and hence is largely ignored in both the collegiate curriculum and the practice in civil life. Hence it is that there are but few men in civil life who are, though previous training, fitted to solve the sanitary problems daily presented to the medical officer.

The profession at large, from whose ranks the personal of the Army Medical Corps is selected, must stand as sponsor for its representation in the military service and ensure that reasonable measures for the promotion of efficiency in the latter are not ignored. We, therefore, commend General Sternberg's bill, to the favorable consideration of the medical men of the United States and urge that such active measures be promptly taken, both individually and collectively, as will bring about much-needed congressional legislation during the coming winter.

ECHOES AND NEWS.

Dr. E. Eliot, Jr., has been appointed attending-surgeon at Presbyterian Hospital in place of Dr. C. K. Briddon, resigned.

New Yellow-Fever Serum.—The Sanitary Institute in Montevideo, Uruguay, it is declared, is preparing a new yellow-fever serum which is considered superior to Professor Sanarelli's.

Tenement-house Committee of the Charity Organization Society has offered four prizes to architects for plans for improved city tenements. The plans submitted are to be exhibited in connection with the tenement-house exhibition to be held this winter in New York and other cities.

Deaf and Dumb School Burned.—The Western Pennsylvania Institute for the Deaf and Dumb, situated at Edgewood, was destroyed by fire on December 14th. It is believed that the pupils, 500 in number, were all saved. The loss is placed at $150,000, with insurance of $100,000.

Japan Stamps Out the Plague.—The Japanese authorities are entitled to much praise for their speed and skill in stamping out the bubonic plague. The disease was not allowed to spread beyond the seven patients originally attacked. All of these died, but they were so well isolated that no new cases were reported.

Dr. Frederick L. Johnson, thirty-one years old, died at his home at Maspeth, Queens borough, on December 11th. He had overworked himself for some time and had developed insomnia. It is believed that he took by mistake an overdose of chloral. His condition was not discovered during the night and he was found dead on the morning after taking the dose.

Dr. Northrup Lectures at Yale.—By invitation of the Yale Medical Alumni Association Dr. W. P. Northrup, professor of Pediatrics in the University and Bellevue Hospital Medical College, delivered an address to them December 13th on "Some Paths of Tuberculous Infection." President Hadley presided at the meeting. Later a reception was given at the house of Dr. Leonard Bacon.

Medical Men in Municipal Life.—The *British Medical Journal* in its recent issue calls attention to the fact that among the new mayors recently elected throughout Great Britain the medical profession is well represented. There were thirteen doctors elected to the office of mayor. It is a sign of the times, says the *Journal*, alike beneficial to the civic life of the nation and honorable to an honorable profession.

International Congress on Tuberculosis.—The British National Association for the prevention of consumption and other forms of tuberculosis is taking steps to organize an international congress to be held in London in the

spring of 1901. Invitations will soon be issued to 600 representative persons and institutions in the United Kingdom to attend a preliminary meeting for the purpose of making arrangements.

Hydrophobia in Washington.—The Department of Agriculture issued on December 12th an order prohibiting the immigration or emigration of dogs to or from the District of Columbia. Dogs with muzzles may, however, be immigrated. The reason for the prohibition is that a hydrophobic scare prevails in the neighboring sections of Maryland and Virginia. The District Commissioners are not pleased with the department's action.

Harlem Hospital. — Dr. Dudley, of the staff, appeared before the Harlem Board of Commerce at 50 West 125th street on the evening of December 11th. He denounced the condition prevailing in the present institution. The hospital is as crowded as a tenement and, under the the circumstances, most unfortunate results follow. Patients have to sleep on the canvas stretchers on the floor. There are no lying-in accommodations and at times the wards are "veritable horrors."

German Sanitary Conditions.—Dr. Leidy of Philadelphia is now in Berlin, where under the direction of Professor Virchow he is investigating diseases caused by animal parasites in food. He finds that such diseases are far more common in Germany than in the United States, their greater prevalence in the former country being due to the popular habit of eating uncooked meats. Dr. Leidy finds typhoid almost unknown in Berlin, probably because of the perfect filtration of the city's water.

The State Board of Charities has disapproved of the incorporation of the Emanu-El Hospital and Dispensary of New York City. Many protests were raised, notably by Dr. J. H. Byrne, the chairman, and Dr. F. R. Sturgis, the secretary of the Committee on Charities and Legislation of the New York Medical League. The principal ground of protest was that the Jewish community on the East Side does not need such an institution. This is one of the early fruits of the new dispensary law.

Red-Cross Help for Boers.—The Boers urgently need succor for the wounded and sick both of their own soldiers and of their British prisoners, America has been appealed to for help, and the American committee to aid Red-Cross work in South Africa has been formed. It in turn has appointed subcommittees in many parts of the country. Money is mostly needed, and those who would contribute must do so quickly. The committee meets at the office of Mr. Bergen, 55 Liberty street, and contributions are received there by Mr. Bergen as treasurer.

Craig Epileptic Colony.—The annual report of the Board of Managers of the Craig Colony, of which Dr. Frederick Peterson is the president, states that since its opening on February 1, 1896, 504 epileptics have been received, of whom 378 remain. When the new buildings now in course of construction are completed the capacity of the colony will be increased to a total of 720 beds. During the past year 95 new cases were admitted. Of these 40 were men and 55 were women; 35 were discharged. The death-rate in the colony during the past year has been but two per centum.

Health Outposts for Europe.—Drs. E. K. Sprague, G. M. Magruder, G. M. Corput, S. B. Gibbs, and W. C. Hobdy of the United States Marine Hospital Service, who sailed on the "St. Louis" on December 14th, will be stationed at European ports to see that all vessels with immigrants bound for the United States have a clean bill of health. Ten other physicians will follow them. Any immigrant-carrier failing to provide a bill of health signed by an American physician at the port of sailing will not be permitted to enter any American port. The doctors will be stationed at the American consulates of European ports.

Diphtheria Epidemics.—The prevalence of diphtheria in Irvington, N. Y., caused the closing of the public school from December 13th to January 2d. Fifteen cases and several deaths have been reported. In Paterson, N. J., there were reported from December 1st to the 12th inst. fifty-nine cases. It is feared the record will be 150 cases for the month. It is believed the condition of the public schools is primarily responsible for the spread of the disease. It is intended to follow the New York City plan of having physicians make daily school inspections. The epidemic is causing great uneasiness, and strict measures are being taken to prevent its further spread.

A $10,000 Suit Settled for $900.—In March last Dr. B. L. Robinson of McLean, N. Y., brought a suit for $10,000 for medical service against G. E. Chalmers of Cortland. The latter is a reputed millionaire. The case was settled on December 15th. In September of 1898 Mr. Chalmers "began to commit suicide" by hacking at his throat with a razor. When he had seriously wounded himself he repented and called for a physician. Dr. Robinson responded, and performed some really difficult surgical work. His patient recovered. The doctor based his charge for $10,000 on the ground that the life of the irresolute suicide was worth that amount. The attorneys for Mr. Chalmers declared that on this accounting the visits made by the doctor would average $1000 for each. The case was settled for $900.

An International Congress on Hypnotism.—A second international congress on hypnotism will be held in Paris from August 12 to 16, 1900, under the presidency of Dr. Jules Voisin. The following questions will be discussed: The formation of a vocabulary concerning the terminology of hypnotism and the phenomena connected therewith; the relations of hypnotism with hysteria; the application of hypnotism to general therapeutics; the indications for hypnotism and suggestion in the treatment of mental diseases and alcoholism; the application of hypnotism to general pedagogy and mental orthopedics; the value of hypnotism as a means of psychological investigation; hypnotism in relation to the (French) law of November 30, 1892, as to the practice of medicine;

suggestion and hypnotism in relation to jurisprudence, and, finally, special responsibilities arising from the practice of experimental hypnotism.

Dr. Harvey Reed Retires from the Wyoming General Hospital.—Dr. Harvey Reed, formerly of Columbus, Ohio, but recently of Rock Springs, Wyo., has resigned the position of medical director of the Wyoming General Hospital, to take effect December 31, 1899. The Wyoming General Hospital is a State institution, and under the control of a political board. When Dr. Reed accepted this position the institution had been in operation for three years, during which time there had been treated 272 patients. During the first year of his service he admitted and treated 313 patients in addition to eight holdovers from the former administration. During the second, which ended September 30th, 1899, he admitted and treated 378 patients, including 28 holdovers from the previous year. In addition to Dr. Reed's resignation, the chief nurse and chief house surgeon also tendered their resignation, and we understand on good authority that several other nurses will resign.

The Coffee Question at New York Quarantine.—The New York Board of Health has finally decided to admit to the docks the coffee ships that have arrived at Quarantine upon which no case of plague has developed. The coffee of "J. W. Taylor," the plague-infected ship, is still held upon the lighters, and cannot be landed until it has been roasted. The plan of the consignees of the ships that were being held at quarantine, to send them to Boston and ignore the action of the New York Board of Health was frustrated by an order from the Secretary of the Treasury, announcing that the ships would not be permitted to go to Boston as that would be participating in coastwise trade. To obviate the dangers of a similar predicament in case of the fleet of coffee ships now en route from Santos, the consignees have arranged to signal the ships outside of New York harbor until they can learn the sanitary condition of them and the likelihood of their passing the New York Quarantine and the Board of Health. If the prospect is not encouraging, the ships will probably be directed to go to Boston. What an absurd state of affairs! This would all be obviated by a national uniform quarantine.

MEDICAL MATTERS IN PHILADELPHIA.

[From Our Special Correspondent.]

SYPHILIS OF THE LIVER—A CASE OF ANTHRAX—DR. DEAVER ON RESECTION OF THE BOWEL—DR. STENGEL ON ANEMIA—GENERAL DISINFECTION OF THE PUBLIC SCHOOLS — HEALTH REPORT FOR THE CURRENT WEEK.

PHILADELPHIA, December 16, 1899.

TWO cases of syphilis of the liver were reported by Drs. J. A Scott and L. N. Boston at the last meeting of the Pathological Society, held December 14th. The first case, that reported by Dr. Scott, occurred in a man of sixty-nine years of age, in whom the initial lesion had developed forty years previously, and had healed without the subsequent appearance of secondary symptoms. Two years ago he first noticed a general enlargement of the abdomen, and in the early part of the present year edema of the feet and ankles became apparent. On his admission to the hospital, in March, 1899, his abdomen was much distended and filled with fluid; neither the liver nor the spleen were palpable. He was tapped six or eight times in all, and a total quantity of twenty-nine gallons of fluid was removed from the abdominal cavity by these operations. The patient finally died from an acute intercurrent infection with erysipelas. At the autopsy it was found that the liver weighed 2200 grams (4.3 lb.), and the spleen 1200 grams (2.3 lb.), both being firmly bound down to the adjacent tissues and organs by dense adhesions, the right lobe of the liver being quite divided into two separate parts by a large, deep scar. The pancreas was dislocated, the head of this organ being found to occupy a vertical position. A chronic fibrinous general peritonitis also existed. Referring to the general symptomatology of syphilis of the liver, Dr. Scott remarked that the common clinical manifestations were usually those of cirrhosis; in differentiating it from other forms of cirrhosis, absence of such symptoms as diarrhea and antecedent digestive disturbances were in favor of syphilis, the presence of a history of primary infection being, of course, most suggestive. Dr. Boston's patient, a woman thirty-two years of age, had noticed for the past six months a progressive enlargement of the abdomen, which she falsely attributed to an existing pregnancy; there had also been occasional attacks of vomiting, some bloody expectoration, and slight hemorrhages of the bowel, due, perhaps, to the prefence of hemorrhoids, from which the woman also suffered. After the aspiration of 176 ounces of fluid from the abdominal cavity, a period of improvement in the patient's general condition followed, but dyspnea and other symptoms again became distressing with the reaccumulation of the ascites, and at a second tapping 144 ounces of clear fluid were removed. The second operation was followed by a good deal of shock and some heart failure, from which the patient rallied but slightly, dying two days later. Autopsy showed that the liver was of a yellowish-gray color, stippled with fine yellowish areas encircled by fibrous bands producing at these points a somewhat depressed area; the organ was distinctly lobulated. Microscopical examination showed that, as a rule, the liver cells were well formed, and that areas of dense fibrous tissue dipped down from the capsule of the organ and extended well into the liver substance. The spleen was slightly enlarged and the peritoneum dormal.

At the same meeting Drs. J. H. Jopson and A. A. Ghriskey reported a case of anthrax occurring in a man of forty-eight years, a worker among raw, green hides in a morocco factory. Following infection through a slight scratch on the forearm, the patient noticed that the infected arm became much swollen, and that a peculiar spot appeared at the site of the scratch—a spot about 1 cm. in diameter, having a minute dark-colored center, and surrounded by sort of a halo of small, pearl-colored vesicles,

eight in number. After incision of the infected member by means of which a small amount of gelatinous matter, but no pus was removed, the patient seemed to improve somewhat, but four days later his temperature became subnormal, and after repeated abortive attempts to bring about reaction, he died. No post-mortem examination was made, but a bacteriological study of the local lesions made during life, gave interesting results. From material obtained from the central bleb-like area three microorganisms were found, a staphylococcus, a streptococcus, and a bacillus. A mouse inoculated with cultures of the bacillus died after a short period, and this fact, together with the cultured peculiarities of the organism, identified it as the bacillus of anthrax. The staphylococcus was regarded as the staphylococcus epidermitis albus, and the streptococcus was unidentified.

At the last meeting of the Academy of Surgery, held December 4th, Dr. John B. Deaver exhibited two patients upon whom he had done the Kraske operation. One was a young man of twenty-five, who had an intestinal growth which microscopical examination proved to be adenocarcinoma, in spite of his youth. Examination of the blood showed 69 per cent. of hemoglobin, 3,400,000 red cells, and 16,000 leucocytes per c.mm. A resection of 3.5 inches of the rectum was made, the external sphincter being also removed. In the second case 4 inches of the rectum was removed. In this case and also in another upon which he had operated control of the sphincter was not lost. Dr. Deaver stated that for some years he had not done an inguinal colostomy, being strongly in favor of the Kraske operation as performed without this preliminary. The function of the sphincter can be retained wherever this structure is not actually involved by the morbid process, and although a temporary fecal fistula has resulted in all his cases, all have finally closed without serious trouble. The speaker did not agree with Senn that these cases can be operated upon without involving the sacrum, believing that the parietal peritoneum cannot be handled so well by this method. The chisel or osteotome is employed, and the sacrum thus divided low down as a preliminary, and then as high up as necessary. In one case the cauda equina was exposed, but no bad symptoms followed this incident. Suturing the anterior part of the bowel is a difficult procedure, but this is rendered easier by saving as much tissue and levator ani as possible. By placing the patient on either side, the legs being strongly flexed, the whole rectum can be resected, and the sigmoid brought down, still retaining intact the sphincter. The wound is packed with iodoform gauze, and allowed to heal by granulation. This method of operation argues in favor of an earlier operation than is usually done in such cases. In conclusion, Dr. Deaver remarked that in his experience artificial ani in the groin or in the lumbar region had not proved satisfactory, and that he would make such an opening only in advanced cases, in order to make death easier, or to make the patient more comfortable for a time. Every case should be explored thoroughly to determine whether the other operation is possible, before colostomy is done.

At the last meeting of the Section on General Medicine of the College of Physicians of Philadelphia, held December 11th, Dr. Alfred Stengel reported a case of splenic anemia occurring in a child of three years. The blood findings were as follows: Hemoglobin, 30 per cent.; red cells, 2,920,000 c.mm.; leucocytes, 9600 per c.mm. Differential count of the latter showed 31 per cent. lymphocytes, monuclear forms 50 per cent., polymorphonuclear neutrophiles 17 per cent., 1.6 per cent. eosinophiles, and 0.4 myelocytes. Erythroblasts were also found. These blood changes followed an acute attack of gastro-enteritis, subsequent to which anemic pallor, seizures of vomiting, and enlargement of its abdomen were noted. The lymphatics, spleen, and liver were enlarged. The case in question was regarded as an instance of marked secondary anemia with enlargement of the spleen, there being, in the reported opinion, no proof of the existence of a true primary splenic anemia.

A general disinfection of all the public schools is to be made, owing to the great prevalence of diphtheria and of other contagious disease among the pupils of the various schools, a condition which has already necessitated the closing of several schools in different parts of the city. The buildings are to be disinfected during Christmas week, so that it is hoped by the new year that every school will be able to present a clean bill of health.

The number of deaths in this city during the week ending December 16th was 445, an increase of 33 over the number reported last week, and a decrease of 36 from the number reported during the corresponding week last year. Returns of contagious diseases were as follows: Diphtheria, 154 new cases, 26 deaths; enteric fever, 32 cases, 3 deaths; scarlet fever, 65 cases, 2 deaths.

MEDICAL MATTERS IN CHICAGO.

[From Our Special Correspondent.]

FIVE CASES OF DIAPHRAGMATIC HERNIA — A NEW PATHOGENIC FUNGUS—RELATION OF MENTAL DISEASE TO LIFE EXPECTANCY—RELATION BETWEEN RECTAL DISEASES AND LIFE EXPECTANCY—EXAMINATION OF WOMEN FOR LIFE INSURANCE—RELATION OF CHRONIC EAR DISEASES TO LIFE INSURANCE.

CHICAGO, December 16, 1899.

AT a meeting of the Chicago Pathological Society, held December 11th, Dr. Charles A. Parker reported five cases of diaphragmatic hernia, three of which were traumatic. The specimens and data of three of these cases were furnished by Dr. L. Hektoen; the other two were observed by the author in the dissecting-room of the same institution. All were found post-mortem. There was no history of ante-mortem symptoms obtained in any of the cases, and in none was there any evidence that the condition had shortened the owner's life. All were adults, one woman and four men. Four were on the left side and one on the right. In no case was there a complete sac, and in but one was there even an attempt at its formation. In the three traumatic cases scars were found in the integument of the lower left chest wall and extending into the deeper tissues, in one making the

union of the cut ends of the seventh and eighth costal cartilages of that side and terminating at a circular opening 1.5 cm. in diameter in the sixth intercostal space in the mammary line; in another leaving an opening in the eighth interspace in which was an adherent fringe of great omentum of the hernia; and in the other there was no noticeable change in the intercostal tissues. The diaphragm was penetrated in its muscular position in all three of these cases, and in nearly the same place, anterior, and to the left. The opening in one was 2 mm. in diameter, in another 5 mm., and in the third 2.5 cm. by 4 cm.

The contents of two of the traumatic cases were simply omentum, but in the third and larger one were the transvere colon, twenty inches long, with its mesentery and vessels, and part of the great omentum, occupying a considerable portion of the left pleural cavity to the left of the pericardium. In this case an incomplete sac formed mostly of great omentum extended through the intercostal opening, and some distance down on the external surface of the chest wall beneath the skin forming an intercostal hernia. Its inner surfaces were not adherent at the opening, and it is possible and quite probable that at times of increased abdominal and thoracic pressure portions of the large intestine were forced into it, forming part of the contents of this most unusual (intercostal) variety of hernia.

Of the two cases considered congenital from lack of evidence of traumatic origin, one was a female and one a male. In the former there existed an opening in the left anterior region of the diaphragm two inches in diameter, transmitting into the left pleural cavity a hernia that consisted of the stomach and first portion of the duodenum, the entire transvere colon and great omentum. As there were very few adhesions to the surrounding structures, there were quite freely movable, so the contents of the hernia probably varied from time to time.

In the male subject an opening 3¾ by 4½ inches occupied a considerable portion of the right half of the diaphragm, and through it extended the larger part of the liver, including most of the right and left lobes, with the gall-bladder into the right pleural cavity, where it was firmly held by strong adhesions. The margin of the opening was free throughout the greater part of its extent, and the hand could be freely passed from the abdomen into the thorax in front of the line.

At the meeting of the Chicago Pathological Society, held December 11th, Dr. Hektoen described a new pathogenic fungus, the sporothrix of Schenck. This fungus was first described by Schenck who isolated it from refractory subcutaneous abscesses of the forearm and arm of a man. Dr. Hektoen obtained the same fungus from a series of similar, very refractory subcutaneous abscesses of the hand and forearm in a boy under the care of Dr. Perkins of Shenandoah, Iowa. The fungus consisted of septate, branching threads; around the ends and along the sides of the branches appear oval and oblong conidia, which, when isolated, greatly resemble yeast bodies. The fungus grows readily on ordinary media and stains by Gram's method; it is pathogenic especially for rats and mice, producing ulcers and chronic abscesses with much connective-tissue formation; only the spores or conidia are found in the lesions. The report was illustrated with a series of excellent lantern-slides.

At a joint meeting of the Chicago Medical Society and the Chicago Medical Examiners' Association held December 13th, Dr. Harold N. Moyer read a paper on "Relation of Mental Diseases and Residence in an Asylum or Sanatorium to Life Expectancy." He said that life-insurance examination, the only purpose of which is to determine probable longevity, furnishes the basis of a contract between insured and insurer. The blank forms for data gathered by the medical examiner might be improved by a form calling for family and personal history to be filled out and filed by the applicant. This would give the examiner wider latitude in passing on the risk, and overcome the tendency of some to sink the spirit of the examination in the latter.

The most important nervous disease in relation to insurance is paretic dementia. The average duration of life after an attack is about three years. The symptoms of this disorder are not covered in the ordinary blank. It is not the outcome of specific diseases, mental strain being the most frequent contributing factor; the slight importance attached to this by the applicant, however, causes it to pass without notice. Where amounts of insurance beyond the supposed means of the individual are applied for, paretic dementia should always occur to the mind of the examiner and a careful inquiry should be made into the immediate history of the applicant.

Dr. Weller Van Hook followed with a paper on the "Relation between Rectal Diseases and Life Expectancy," in which he discussed the commoner diseases of the rectum, hemorrhoids, stricture, abscess, fistula, gonorrhea, ulcerations, prolapse, and carcinoma, in causal relation to one another and in relation to life expectancy.

Dr. Denslow Lewis discussed the "Examination of Women for Life Insurance." He said that life insurance is a business proposition. The basis of calculation in life insurance is not perfection of health, but a standard. The average life probability of standardized groups is the basis of insurance statistics. The perpetuity of life insurance and the reliability of actuarial computation depend on the determination of the standard. The prescribed examination of women fails to discover many important pathologic conditions which affect the risk and influence the standard. Dangers of child-bearing are now considered compensated by diminished exposure, more regular mode of life, etc. Increased moral risk is recognized in young divorced widows, and the influence of economic and sociologic relationship is appreciated. Gynecologic examinations should be made in every applicant to determine pathologic conditions not discovered by the usual form of examination which was devised originally for investigation of men. Hardening of the breast is a cause for rejection unless the sequel of recent abscess. If the finger in the vagina cannot touch the promontory of the sacrum the conjugate diameter may be assumed to be sufficient for the parturition. Lacerations

of perineum and cervix are especially important when infected. Leucorrhea usually indicates infection which should be investigated. Infection is always a potential danger, for the limits of possible extension cannot be determined. The differential diagnosis for insurance purposes is unnecessary. Tenderness in either fornix and any intrapelvic deviation from the normal condition, as determined by bimanual examination, is sufficient cause for postponement or rejection.

Dr. J. Homer Coulter dealt with the "Relation of Chronic Ear Diseases to Life Insurance," confining his remarks to the subject of chronic suppurative otitis media. An acute suppuration of the ear will, if left alone, tend to become chronic, and many cases improperly treated will tend either to seriousness or chronicity; hence, a complete and fully detailed report of the case is necessary in examining an individual for life insurance. Medical directors generally do not accept an applicant for insurance at ordinary rates who gives a history of chronic or repeated attacks of acute inflammatory affection of the ear. While this rule may work injustice in some cases, it is the only course to protect the companies, except in those few rare instances where the applicant is willing to pay for the services of an expert otologist who can give a technical report upon his case. It is not because of the proportion of fatalities that occur in suppuration of the middle ear that the speaker would urge its particular importance in relation to life insurance, but rather because of the large number of suppurating ears met in practice, any one of which is liable to go on to mastoid involvement, with sinus or brain complication, and death. Admitting the seriousness of this class of cases generally, even with the best treatment, and also the practical fact that those afflicted with chronic suppuration of the ear are not considered insurable at ordinary rates, the very pertinent question arises, can these applicants become safely insurable risks by any method of treatment or operation? Or, Are any of them with less prominent symptoms only being manifest, in their present condition, deserving of a first-class rating? Most important in this connection is the necessity of an examiner in whom the medical director places implicit confidence. If from such an examiner, using appropriate instruments, a complete report is received as to the functional activity of the ear, and in connection therewith a carefully detailed history of the symptoms of the case from the time of the first attack, then will the medical director be in a position to determine whether or not the applicant is an insurable risk. If the applicant be entirely free from attacks of tinnitus, vertigo, headache, disturbance of vision, or itching in the ears, for a period of several years, then he may be considered safely insurable so far as the ears are concerned.

Horse Sickness in Natal.—One of the worst enemies with which the British cavalry in Natal will have to contend goes by the names of "dikkop" and "throat sickness." It is a species of anthrax. Experts describe it as a soil-developed disease, produced by a small living organism, of a vegetable nature, known as the Bacillus Anthracis.

SPECIAL ARTICLE.

TO THE MEMBERS OF THE MEDICAL PROFESSION IN THE UNITED STATES.

THE cause of humanity and of scientific progress is seriously menaced. Senator Gallinger has again introduced into Congress the bill for the "Further Prevention of Cruelty to Animals in the District of Columbia," which he has so strenuously and misguidedly advocated in the ast two Congresses. Its present number is "Senate Bill No. 34." Twice the Committee on the District of Columbia has also unfortunately and misguidedly reported the bill with a favorable consideration. The bill is speciously drawn to seem as if it were intended only in the interest of prevention of cruelty to animals. The real object of the bill is twofold: first, to prohibit vivisection and, secondly, to aid the passage of similar bills in all the State Legislatures.

I need hardly point out to you that this would seriously interfere with or even absolutely stop the experimental work of the Bureau of Animal Industry and the three medical departments of the Government, the Army, the Navy, and the Marine Hospital Service. The animals themselves might well cry out to be saved from their friends. No more humane work can be done than to discover the means of the prevention of diseases which have ravaged our flocks and herds. All those who raise or own animals, such as horses, cattle, sheep, pigs, chickens, etc., are vitally interested in the preservation of their health and the prevention of disease.

The inestimable value of these scientific researches as to the prevention and cure of disease among human beings it is superfluous for me to point out. Modern surgery and the antitoxin treatment of diphtheria alone would justify all the vivisection ever done.

As my attention has been called officially to the introduction of the bill I take the opportunity of appealing to the entire profession of the country to exert themselves to the utmost to defeat this most cruel and inhumane effort to promote human and animal misery and death and to restrict scientific research. It is of the utmost importance that *every physician* who shall read this appeal shall *immediately* communicate especially with the Senators from his State, shall also invoke the aid of the Representatives from his or other districts in his State and by vigorous personal efforts shall aid in defeating the bill.

It is especially requested also that all of the National, State, and County societies at their next meeting take action looking toward the same end. If regular meetings are not soon to be held special meetings should be called. Correspondence is invited from all those who can give any aid.

The Committee on the District of Columbia consists of Senator James McMillan (Michigan), Chairman, and Senators J. H. Gallinger (New Hamshire), H. C. Hansborough (N. Dakota), Redfield Proctor (Vermont), J. C. Pritchard (N. Carolina), Lucien Baker (Kansas), C. P. Wetmore (Rhode Island), C. J. Faulkner (W. Virginia), Thomas S. Martin (Virginia), Wm. M. Stewart and

Richard Kenney (Delaware). Personal letters may be addressed to them or to other Senators. Petitions should be addressed to the Senate of the United States.

W. W. KEEN,

President of the American Medical Association.

PHILADELPHIA, DECEMBER 16, 1899.

[The urgency of this appeal and the value and importance of prompt action by the individual members of the profession as well as the organized societies and associations cannot be too vigoriously insisted upon. Let us one and all stand shoulder to shoulder in this matter, and make it plain to Senators and Representatives that the solid vote of the profession in the County, the District, and the State, regardless of party politics, will be cast against the man who fails in his duty in this matter. The bill is a blow aimed at the very foundation of scientific medicine, and that to us is the most vital question that can be raised. A flood of remonstrance, such as is contemplated in this appeal, cannot fail to open the eyes of Congressmen to the serious nature of the bill and the earnestness of the profession.—ED.]

CORRESPONDENCE.

NOTES ON MANILA.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—As a member of the Medical Commission sent by the Johns Hopkins University to study the tropical and other diseases in the Philippine Islands, I send you a few notes gathered from personal experience which may prove of interest to your readers.

The climate is continually that of summer, the heat, especially, during the wet monsoon being peculiarly moist. It is the constancy of the heat through night and day, together with the high degree of humidity, rather than the actual elevation of the temperature which makes the climate trying. The northeast monsoon prevails from October to April, and corresponds to the finest portion of the year in the Philippines. During these months the climate leaves but little to be desired. May and June are the two hottest months in Manila, and these months, together with the beginning of the wet season, are the most difficult to bear. The wet season corresponds to the period of prevalence of the southwest monsoon. Typhoons or circular storms may occur at almost any time, but espepecially when the monsoon changes. They cause enormous losses of life and shipping, though now, through the activity of the Jesuit fathers at the Manila observatory, the approach of a typhoon is always recognized at an early hour, so that storm signals can be raised along the coast and the advent of the storm be communicated to Hong Kong by submarine cable.

Modern Manila is a composite town consisting of the old walled city and a large number of suburbs, each with its own special name and streets The same name may be given to a street in two different suburbs, so that in giving one's address it is often necessary to associate the name of the suburb with that of the street. Outside the walled city the main business portion of the town is in the region known as Binondo. The aristocratic residence quarter for the Spaniards was the suburb called San Miguel. In this district was the Governor-General's residence and the homes of many of the Spanish officers and foreign consuls. In Ermita and Malate most of the rich foreign traders reside. Tondo was almost a purely native district, and it will be remembered that it was here that the worst outbreaks occurred during the insurrection. This portion of the town was almost entirely burned down. Other districts are Concepcion, Santa Cruz, Quiapo, Sampaloc, and Paco.

The fortifications about the old city consist of bastioned and battlement walls built at the end of the sixteenth century. Just outside the walls, except where the city is naturally surrounded by water, there are deep moats said to be paved at the bottom and provided with sluices with which they can be filled with water from the Pasig River. These moats are now partly full of water, the edges are overgrown, and there is much mud and organic refuse in the bottom. An attempt was once made to cleanse the moats, but was soon abandoned, as it was feared that the removal of the stagnant water and putrid vegetable material might give rise to a severe epidemic. The city is lighted by electric light; the paving is for the most part inferior. A tramway runs through the town, the cars being drawn by ponies, most of them in wretched physical condition. There were several daily papers in Spansh times, but nearly all of these have given place to English dailies since the American occupatiou. The population of Manila, including the suburbs, was estimated in 1896 to be 340,000. The total population of the islands is probably less than 8,000,000, of which 100,000 are Chinese. There were at the time of the outbreak of hostilities about 25,000 Europeans in the Archipelago.

The city of Manila is supplied with excellent water, which is pumped to a large reservoir situated several miles from the city, and thence conducted into the city by large pipes.

The hospitals in Manila may be conveniently divided into the military hospitals and the civil hospitals. The American army hospitals consist in the first place of two large institutions, the First Reserve Hospital situated in Concepcion and a Second Reserve Hospital located in Malate. Besides these two there are situated in different parts of the city various district and regimental hospitals which attend to minor ailments of soldiers and serve as feeders for the larger institutions when more severe diseases are encountered. Colonel A. A. Woodhull is the surgeon in chief of the army forces in the Archipelago. His extensive medical experience, together with his unusual executive ability, largely account for the excellent administration which one finds in Manila. The First Reserve hospital, under the charge of Major Crosby and a large force of surgeons and physicians, has some 1200 beds, and to it come most of the gunshot wounds and a large proportion of the very acute diseases. The wounded insurgents are also cared for here. The Second Reserve Hospital, under Major Keefer and a number of assistants, was originally intended as an overflow hospital for the First Reserve and for the reception of con-

valescent and less severe cases. As matters have turned out, however, this hospital has come to contain as severe cases as the First Reserve. The hospital-ship "Relief," lying in the harbor, also received acute surgical and medical cases As a convalescent hospital the institution on Corregidor Island has proved most valuable. The air there is cool and fresh, and patients sent there have almost invariably done well. The wounded and sick from the various regiments on the fighting line, and the stations outside Manila are brought in by railway or by wagon-train to the Manila hospitals. At the First Reserve Hospital there is an excellent laboratory, which during our visit was under the charge of Lieutenant Strong. Through the courtesy of Colonel Woodhull and the hospital authorities this laboratory was placed at our disposal, and all of the patients in the various hospitals were freely made accessible to investigation. Clinical studies were conducted in the wards, and in the morgue autopsies were conducted. Bacteriological examinations and studies of the blood, together with animal experiments, were made in the laboratory.

Of the city hospitals in Manila may be mentioned San Juan de Dios in the walled city, the Hospital de la Convalecencia and Hospicio de San José, on an island in the Pasig River, and St. Lazarus, the asylum for lepers, in the ward of Santa Cruz. These civil hospitals were also made accessible to the work of the medical commission through the courtesy of Major Frank Bourns of the Provost Marshal's department. Dr. Bourns, who had charge of the sanitation of the Manila, deserves great praise for the energy he has displayed in reorganizing the sanitary regulations

When the American army first went to Manila there was a large mortality among American soldiers from smallpox. Among the natives the disease was as common as measles or scarlet fever, and not much more feared than these diseases. A large proportion of the faces one sees in the streets are pitted. Dr. Bourns immediately undertook the vaccination of the whole population of Manila. He had to use at first imported virus, but this being unsatisfactory on account of imperfect communications and the very hot climate, an attempt was made to prepare a virus in the city. Cattle being unattainable owing to the insurrection, he was forced to institute a *carabao* (water buffalo) vaccine farm. This proved to be very satisfactory, and the lymph produced is as effective as can be desired. Some eighteen Filipino physicians were engaged to vaccinate the native population, and the work was done so thoroughly that when we were in Manila smallpox had been almost entirely stamped out.

Soon after our arrival in the islands we had the opportunity of studying a large outbreak of beri-beri, and Colonel Woodhull asked us to examine a number of Filipino prisoners confined in the old Spanish prison at Cavite suffering from the disease. No less than 200 of the 1000 prisoners there developed beri beri, and the various types could be studied with ease.

It is customary to divide cases of beri-beri into three main types: (1) The edematous form, (2) the paralytic form, and (3) the mixed form. In nearly all cases circulatory disturbances are marked early in the disease. There is palpitation of the heart and throbbing of the peripheral vessels. Physical examination shows enlargement of the heart, especially of the right side. This enlargement is due chiefly to dilatation, and is accompanied with very marked cardiac distress. The patients cry out as one goes through the ward, "Mi pecho, mi pecho!" Digestive disturbances are also common at the beginning. There is nausea, anorexia, and frequently vomiting. In the edematous form the legs begin to swell, and the edema gradually extends upward until in some cases the whole body is involved. In very severe instances there is hydroperiteneum, hydrothorax, and hydropericardium. Many of the latter cases terminate fatally.

In the paralytic form without edema disturbances of locomotion come on gradually. The symptoms resemble closely those of peripheral neuritis, but differ somewhat from the latter disease as ordinarily met with. Many observers believe that no actual neuritis exists, but only a degenerative process. Pain is usually present in some part of the body. Pressure on the muscles of the calf usually causes excruciating pain. Sensation may or may not be considerably involved. The reflexes also vary with the distribution of the neural lesions. After a time muscular atrophy sets in, and these patients may become much emaciated.

In the so-called mixed form edema and paralysis are associated. The clinical and epidemiological history of the disease speaks strongly in favor of an infectious nature. The symptoms are those of a severe intoxication.

Cultures made from the blood from a large number of cases yielded negative results. Careful autopsies were conducted on those who died while we were in the islands, and the pathological material collected was brought back to this country. It will be thoroughly studied and the results published later.

LEWELLYS F. BARKER, M.D.

BALTIMORE, MD.

OUR LONDON LETTER.

THE "HEALTH ARMY" OF THE TRANSVAAL COMPAIGN—STRIKING CASE OF LEPROSY AT THE POLYCLINIC — NEWCASTLE CONFERENCE ON MEDICAL POLITICS—GOVERNMENT BY SMALL AND IRRISPONSIBLE OLIGARCHIES — DEMAND FOR "ONE PORTAL" TO THE PROFESSION— MEETING OF GENERAL MEDICAL COUNCIL—PROPOSED RECOGNITION OF "FOREIGN DEGREES."

LONDON, December 9. 1899.

AS usual our profession is in no whit behind in the present schemes of philanthrophy for the care of the families of reservists called to the front. Ten days or more ago several physicians proposed that the profession agree to treat the wives and families of soldiers without fee and this has been cordially responded to upon all sides, and lists are being forwarded to the head military authorities in each district of the names of doctors willing to volunteer for this gracious service.

A most typical case of leprosy in a Norwegian sailor,

showing the brownish bosses on the forehead, the thickening and flattening of the bridge of the nose, the loss of the eyebrows and sclerosis with anesthesia of the skin of the hands and feet, was shown at the Polyclinic this week by Mr. Hutchinson. The part played by the anesthesia in some lesions of the disease was well illustrated in the enormous scars which marked the hands, the largest of which had been due to the patient resting his hand against the edge of a stove and not noticing the injury until quite severely burnt. This makes the eighth case of leprosy shown in the surgical clinic at the college in the past five months.

The conference on medical politics held at Newcastle the past week was a meeting of much importance and significance. It was called primarily for the purpose of enabling the three members of the General Medical Council elected by the direct vote of the profession at large, Mr. Horsley, Mr. George Brown, and Dr. Glover, to report to and consult with their constituents in that part of the kingdom on some important questions of medical politics. Indeed, it may be best described and is generally referred to as a conference on medical politics. Mr. Horsley's address was a vigorous comment upon and demand for the reform of the method of electing the great governing bodies of the profession, the Colleges of Physicians and Surgeons, and the General Medical Council. The situation in all these bodies is one singularly like that in our own United States Senate, in that they are elected not by the direct vote of the profession but by a variety of small corporations and organized bodies which, like State Legislatures, can be "packed," so that in Mr Horsley's vigorous terms, "our unfortunate profession is governed by a series of small oligarchies who regard themselves as entirely irresponsible to the great body of practitioners "

As we have already pointed out the proceedings of the business sessions of the British Medical Association are really little better than a farce, on account of the almost absolute power possessed by the General Medical Council, supposed to be elected by the association, and the Councils of the College of Physicians and College of Surgeons which are both elected by a small and comparatively select body numbering scarcely a tenth of the total membership of the colleges, and turning an absolutely deaf ear, as shown in the late account of the Council of the Royal College of Surgeons in regard to the new charter, to all appeals to admit the mass of their constituents to even a partial voice in their election. And as both of these governing bodies are composed chiefly of consultants or specialists it may be imagined how easily questions affecting the general practitioner can be shelved or delayed in settlement.

Sir George Brown's address dealt chiefly with the most anomalous and unsatisfactory condition of the hopeless variety of degrees or qualifications entitling to practise in England and made a vigorous plea for the institution of, what has now come to be quite generally demanded by the rank and file of the profession, a "one portal" system, by means of a State Examining Board, instead of the ancient and cumbrous corporations which now perform this function. Such, however, is the power of precedent and the respect and affection for established usage in England that we fear it will be long before this "council of perfection" can take actual practical form.

Dr. Grover devoted himself chiefly to the burning question of medical practice, and urged the formation of a strong and competent conciliation board which should plan some "modus vivendi" between the clubs with their nearly three million members and capital of nearly $120,000,000, and the hitherto comparatively scattered and unorganized medical profession. He recognized frankly that contract medical practice would have to be accepted for the present at least as a feature of medical work and the best possible terms should be made with it. The discussion which followed was keen and interesting, the proceedings lasted altogether nearly five hours in continuous session, and from the general feeling of approval in the profession it seems likely that these meetings, inaugurated we believe by Mr. Horsley, will be held in every section of the Kingdom and become an important factor in the development and protection of our professional interests.

The meeting of the General Medical Council which is being held this week will deal with several important questions, among them the ever recurring one of contract medical practice and the dispensing of drugs by physicians, this latter being given special point by the painful death of Dr. Dick, reported some months ago, from an overdose of his own medicine, taken to re-assure a patient. The third main subject is of some interest to American practitioners, *viz.*: "medical reciprocity," as it is termed, in which the question of recognizing the degrees of at least certain colleges and bodies in foreign countries, as entitling to practise in England, in return for similar concessions as to English degrees will be considered.

This has been referred to the council in practical form by no less an authority than the British Government, on the basis of a proposition from the Italian ambassador, asking whether if English practitioners were admitted to full privileges in his country, Italian practitioners could be granted similar rights in England and her colonies. As on account of the rapidly increasing winter colonies of English and Americans in the South of Europe this privilege is one greatly coveted by English medical men, it looks as if some positive action were likely to be taken, although there is at once a most powerful opposition to the granting of similar privileges to Italian practitioners here. And though no formal application has been made from any American body or practitioner in this regard, the cry has already been raised that if this door be opened, it will finally lead to the flooding of England with American medical men attracted by the large American colony, or that English students will flock to America and return decorated with the shorter-term American degrees.

Plague Mortality in Hong Kong.—The Governor announced at a meeting of the Legislative Council that the total number of deaths of bubonic plague that had occurred at Hong Kong during the present year was 1413.

TRANSACTIONS OF FOREIGN SOCIETIES.

GERMAN SCIENTISTS MEETING AT MUNICH—NANSEN'S POLAR DISCOVERIES—RADIOGRAPHY IN RELATION TO SURGERY—THE NATURE OF ASTHMA—POSITION OF THE STOMACH—TREATMENT OF SACRO-ILIAC TUBERCULOSIS—AN UNUSUAL OUTCOME OF ACUTE OSTEOMYELITIS—IMPLANTATION OF THE UTERUS FOR THE CURE OF FISTULA. PERFORATION OF INTESTINE FROM INGESTED BONE—GOOD AND BAD RESULTS FROM X-RAYS—A COLLECTION OF LYMPH FOLLOWING INJURY—HEREDITARY GOITER—HEREDITY A FACTOR IN CYSTIC KIDNEY.

THE Seventy-first Convention of German Scientists and Physicians, held at Munich from September 17th to 23d, was opened by several addresses of historical and local interest. The Arctic explorer NANSEN, in an address profusely illustrated with lantern-slides, described the character of the Siberian coast and of the islands lying to the north of it. He made the most interesting discovery that the supposedly shallow Polar Sea really possesses a depth of more than 4000 meters (nearly two and a half miles). The "lifting" of the polar ice is due, he said, to the influence of warmer streams of water acting upon it from beneath. At various places in the ice are found fresh-water lakes, which afford not only excellent drinking-water, but have their own fauna and flora. At no place did he find the temperature of the air below —53° C. (—63° F.), while on the main land of Siberia there has been noticed a temperature fifteen degrees lower than this. For this reason and others Nansen is convinced that at the very Pole in summer birds and perhaps also walruses may be found.

BERGMANN spoke of the possibilities of radiography in the treatment of surgical disease. He outlined the successes already accomplished with the help of the X-ray, but he did not take as rosy a view of its possibilities in the diagnosis of internal troubles as some others have done. In military surgery and in the treatment of deformities the success of the X-ray is well known.

In the Section for Internal Medicine RIEGEL spoke of the treatment of asthmatic attacks. By experiments made to determine the part played by the bronchial muscles in such attacks he concluded that asthma, whether of an idiopathic or reflex nature, is produced through the influence of the vagus nerve. This being the case, the various narcotics which have been employed should be laid aside, and an attempt should be made to reduce the irritability of the vagus nerve. For this purpose no remedy is superior to atropin. In many cases a single subcutaneous dose will suffice to cut short an attack.

MEINERT disputed the idea of Rosenfeld that a horizontal position of the stomach is pathological, and that the only normal position is vertical. The position of the stomach is different in different people. Moreover, it is determined to a large extent by the condition of the surrounding organs. In slim individuals the transverse position may be normal, while in others, especially in women, the normal position may be a vertical one.

In the Section for Surgery, BARDENHEUER advocated resection of the sacro-iliac synchondrosis for tuberculosis. The trouble is almost always a primary local one, and is usually found in men in the third decade of life. The sacrum is often affected so that the disease may extend through it into the corresponding joint of the other side. The chief symptoms are pains in the back, made worse by long standing, and projected downward along the sciatic nerve; pain on pressure upon the joint either anteriorly or posteriorly, produced also by pressure on the iliac crests, and the formation of abscess, appearing either below Poupart's ligament or under the gluteal muscles or in the iliac region or behind the joint. Such patients untreated suffer from long-continued suppuration with amyloid degeneration, to be followed usually by tuberculosis of the lungs. Resection of the joint as soon as an abscess appears gives a chance of recovery. The mortality from the operation in his hands has been thirty per cent.

MULLER described an unusual outcome of acute osteomyelitis which he found three times in 400 cases. The disease, instead of resulting in an abscess and the formation of a fistula, produced a limited callous which clinically gave the appearance of a malignant tumor, such as sarcoma, rather than that of osteomyelitis. In two instances such a tumor was movable. In the center of the induration was a granulating cavity containing a small sequestrum.

In the Section for Obstetrics and Gynecology FREUND spoke of the final results of implantation of the uterus for the cure of obstinate fistula and total prolapse. The operation consists in tilting the uterus backward and sewing it into the fistula which other operations have failed to cure. In young women the permanent result of the operation was found to be cessation of menstruation. The continence of the bladder and rectum was perfect, as was the cure of the prolapse in older women. The possibility of coitus was removed except in certain instances in which the whole cavity of the uterus became dilated and its walls thin and soft. In all patients there was a notable atrophy of the uterus.

WERTHEIM described his method of vaginal implantation of the uterus for the relief of prolapse, which is a modification of the method recommended by Freund. The results were excellent. A short time after the operation the anterior wall of the uterus which lies bare in the vagina begins to skin over, and after eight or ten weeks this process is so complete that the abnormal condition is scarcely recognizable. Pain is so slight that the entire operation may be carried out without an anesthetic, an advantage in the case of certain elderly patients. By his modification of Freund's operation the possibility of coitus remains undisturbed.

AT the session of October 20th of the Imperial Royal Society of Vienna, BUDINGER showed a portion of the small intestine of a man who died of acute peritonitis. He had been ill for eight days with pain in the lower portion of the abdomen, and an incision had been made into a tender tumor under the supposition that it was a strangulated hernia. It proved to be an abscess cavity in a small hernial sac, and in it was found a sharp-pointed piece of bone about an inch and a half long.

There were two complete perforations through the wall of the small intestine. The gut was resected and sewed up, but the patient died of acute peritonitis.

SCHIFF spoke of the two different ideas held by different surgeons regarding the possibility of injury by prolonged exposure to the X-rays. Von Bergmann recently expressed his opinion that the X-rays are incapable of having either an injurious or beneficial effect, while others have reported marked improvement in various skin affections by the proper use of the apparatus. As an illustration of the latter, he presented some patients who had suffered from sycosis and favus, and whom he had presented to the same society a few months previously They were all cured by the radiotherapeutic treatment, and up to that time there had been no sign of recurrence. The rapid and complete cure of favus was especially noteworthy.

At the session of October 27th KAPOSI showed a patient as an illustration of the injurious effects of the X-ray. An old man whose hand was frequently exposed to their influence for the purpose of epilation suffered from a dermatitis of the back of the hand, which was followed in spite of most careful treatment by ulceration, and finally necrosis of the extensor tendons. The speaker mentioned a number of other instances in which long-continued erythema, eczema, necrosis, and gangrene had developed three or four weeks after exposure to the X-rays.

BENEDIKT called attention to the fact that these injurious effects followed a therapeutic use of the rays, and that a short exposure for diagnostic purposes is in no way dangerous. In this opinion Kaposi and others concurred.

At the session of November 17th LANGER showed a coachman who had slipped in getting down from his cab, and scraped his back and left thigh in falling. In the right lumbar region some days later a soft tumor made its appearance about three times the size of the palm. The skin over it was slightly reddened, and it fluctuated plainly. The explanation given was that the scraping injury loosened the subcutaneous tissue, and that an effusion of lymph took place in the cavity thus formed. This is a pathological condition which has been studied by Gussenbauer. The resorption of such cystic deposits of lymph takes place very slowly. Pressure and the injection of irritating solutions having failed to accomplish this purpose, the cavity should be incised and allowed to granulate.

At the Berlin Medical Society, October 18th, HOLLANDER presented five sisters, all of whom were suffering from a diffuse hyperplastic form of goiter. No one of them presented serious symptoms of the nervous or circulatory systems. The chief interest in these cases lay in the fact that they were undoubtedly examples of hereditary goiter. The mother of these young women, as a girl, had lived in a goiterous district and had early developed a large goiter. She moved afterward to Berlin where she married and has lived there ever since. She had seven children, six of them being girls. Each one of the girls developed a goiter when about eleven years of age. Some of the growths were sufficiently large to interfere with respiration. Operation upon a goiter of this type is inadvisible as it usually reacts favorably under iodin either externally or internally administered. One of the patients received thyroid extract for about a month with a negative result.

At the session of November 1st ISRAEL showed a malignant tumor which had developed from an undescended testicle in a patient aged thirty-nine years. The attention of the patient had never been attracted to his inguinal region until a few months before when slight pain caused him to examine himself and he found a small prominence in the lower portion of the abdomen especially on the right side. At operation, the tumor was found to be retroperitoneal. Its under surface was in close contact with the external iliac artery and the bladder. Its removal was extremely difficult, but it was accomplished without injury to the surrounding structures. Microscopically it was found to be an alveolar sarcoma.

SOCIETY PROCEEDINGS

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Proceedings of the Twelfth Annual Meeting, Held at New Orleans, La., December 5, 6, 7, 1899.

DECEMBER 5.—FIRST DAY.—AFTERNOON SESSION.

(Concluded from page 814.)

DR. LEWIS S. MCMURTRY of Louisville, Ky., read a paper on

RECTOVAGINAL FISTULA.

He said that excluding cancer extending from the cervix uteri, rectovaginal fistula is due to traumatism, not to the compression of the tissue, as is vesicovaginal fistula, but extensive rupture of perineum involving the rectovaginal septum, cicatrizing inferiorly, but leaving a perforation above where the septum is thin and permits contact of vaginal and rectal mucous membranes, thus uniting these membranes and making a permanent opening. Wounds made in instrumentation through the vagina, and the pressure of foreign bodies retained in the vagina sufficiently long to produce ulceration and necrosis, are among the rare causes of this lesion.

The most common site is in the lower portion of the vagina, just above the sphincter muscles, and at the point already indicated where the septum is thin and the mucous surfaces are in close proximity one to the other. The opening is usually very small, and the mucous membrane is reflected around like a fringe, making its detection more amenable to touch than to sight.

The method usually applied to the repair of vesicovaginal fistulæ, whereby the edges are freshened in a funnel-shaped denudation, will rarely succeed in repairing a rectovaginal fistula. The action of the anal sphincter, the penetration of fecal matter, and the sparse layer of tissue prevent repair by this method. The divulsion of the sphincter muscle will not suffice to overcome this obstacle to success in the large proportion of cases. Ex-

tensive cicatricial deposit is another obstacle to repair by this simple procedure. The operation, in consequence, is resolved into a modified perineorrhaphy, by which the fistula is transformed into a complete tear of the perineum. The method of flap-splitting popularized by the late Mr. Lawson Tait is preeminently applicable to this procedure. By this method broad surfaces are supplied without loss of tissue and it permits gliding of the vaginal and rectal orifices of the fistula so as to interpose firm and healthy tissues. In exceptional cases, where the fistula is so low down as to be within the grasp of the sphincter, it will be best to divide the septum vertically, freshen liberally the margins of the fistula, and suture the surfaces as in complete laceration of the perineum.

In a very limited class of cases, wherein the fistula is small and cicatricial deposit is not extensive, a simple denudation and suturing after divulsion of the sphincter ani muscle might succeed. The flap-splitting method already mentioned would be found most applicable and should be preferred for general application. Vertical division of the septum should be the first step of the operation in low fistulæ with extensive cicatricial deposit, and the operation is then resolved, after paring the edges of the fistula into the operation for complete tear of the perineum. It will rarely be necessary to use buried sutures; when used, these should be of catgut and should be introduced after the Lembert plan. As already stated, the flat-splitting operation of Tait has the greatest field of usefulness in this procedure. The following case is of special interest, both on account of the unique cause of the fistula, and the consequent deduction that a very simple and common gynecological appliance is not without danger under certain circumstances.

Miss C. W., aged thirty-one, never married, a teacher, was the subject of a backward displacement of the uterus. In August, 1899, she applied to a physician for treatment, and a metallic pessary of the Hodge pattern was inserted. The pessary was placed on a Thursday by the physician who had referred the case to Dr. McMurtry, and the patient returned to her home some thirty miles distant from the physician. On the second day the patient began to suffer pain, which increased day by day, and when examined by the physician on the Monday following, the pessary was found protruding into the rectum and was removed per anum. When the patient was referred to him on October 6th, there was an opening in the recto-vaginal septum just above the anal sphincter of oval form that would readily admit the end of the little finger. The operation consisted of divulsion of the sphincter, separation of the vaginal mucous membrane, freshening the edges of the fistula, and suturing with Lembert sutures of catgut the rectal portion of the fistula, gliding and suturing the vaginal mucous membrane. Union was prompt and perfect, and the patient is now quite well.

DR. C. JEFF MILLER of New Orleans read the report of an interesting case of what he and others considered an ossified uterus. He presented the specimen.

SECOND DAY—MORNING SESSION.

DR. W. D. HAGGARD of Nashville, Tenn., contributed a paper on

THE SURGERY OF BILIARY CALCULI.

He emphasized the fact of the frequent finding of gall-stones in the abdominal cavity, but said their unsuspected existence was not a valid contraindication to operation in cases which, owing to certain complications, menace well-being and perhaps life itself. After enumerating the usually assigned cause of gall-stones, he impressed the undetermined probability of infection. The continuous pain in inflammatory and suppurative conditions of the biliary passages was contrasted with the intermittent and paroxysmal pain from biliary concretions. In connection with the diagnosis, the fact that jaundice was not essentially a sign of gall-stones was emphasized, and waiting for icterus as an evidence of their existence was hurtful.

The relatively small number of operations, compared with the frequency of the disease, indicated that they were either overlooked, failed to give rise to serious trouble, or that the symptoms were taken for other diseases. Surgery of the gall-bladder was almost perfected, but the management of calculi in the ducts by various methods was yet unsettled.

The following case of cholo-cholecystotomy for chronic catarrhal cholangitis with gall-stones was reported:

B. J. G., white, male, aged twenty-seven years. He had his first severe attack of biliary colic attended with tenderness and jaundice in February, 1897. He had had a severe light attack of hepatic colic some weeks before. He was operated on the day after he was taken with the severe attack by Dr. J. F. W. Ross of Toronto. A number of stones were removed, a fistula made, and a drainage-tube kept in for two weeks. The fistula remained open until June, 1897, when Dr. Ross closed it by suture, and the man, who had been in bed the whole of four months, was up in a week. In November, 1897, he again had a number of attacks of colic and jaundice, which kept up intermittently until March, 1898, when Dr. L. McLane Tiffany of Baltimore opened the gall-bladder, but finding no stones he closed it by immediate suture, fixing it to the abdominal wall, and closing the incision throughout. In June of the same year, while still in the hospital, he was again seized with attacks of colic and transient jaundice, which, in the absence of Dr. Tiffany in Europe induced his assistant, Dr. I. R. Trimble, to again open the gall-bladder for exploration. Dr. Trimble found no stones, and thought he succeeded in passing a rubber catheter through the cystic duct, and thence into the duodenum. The gall-bladder was sutured and attached to the abdominal incision, which was closed by buried and superficial silkworm-gut sutures. On July 3d he had received a blow on the skull with a piece of wood in the hands of a drunken assailant, which resulted in a fracture of the skull, which was elevated by Dr. Robert Pillow of Columbia, Tenn.

In August, 1899, fourteen months after the third gall-bladder operation the pain and colic returned, and were rather frequent and more severe than ever before. On October 1st he had a spell that lasted four days, and could obtain no relief from anything. He came to see Dr. Haggard in Nashville, and while there had one of the worst attacks he had ever seen of biliary colic. He gave

the patient 2¾ grains of morphin hypodermically in less than three hours, without any appreciable effect on the agonizing pain. He was not accustomed to taking morphin, and ⅛ grain after the operation had a very happy and full effect.

On November 12, 1899, in the presence of jaundice, which had existed pitifully for two months, Dr. Haggard made an exploratory operation through the old scar parallel with the ribs. As the gall-bladder was attached to the parietes it was opened, and a black, tarry fluid was found therein, and one single, large, gall-stone, soft, and perfectly black, and somewhat larger than a cherry stone, together with some smaller crystal-like stones. An effort was made to catheterize the ducts, as had been reported to have been done before without success. The gall-bladder was irrigated and packed with gauze temporarily. It was then dissected from the parietes below and a careful palpation of the ducts was made, but no other stones could be detected. The adhesions were considerable, as the result of so many previous operations and such long-continued inflammatory trouble, and the gall-bladder was much contracted. Kelly, Senn, and Murphy had all advised a cholecystectomy, but after he found no calculus obstruction to account for the recent colic and existing jaundice, he concluded it must be a chronic catarrhal cholangitis with inflammatory obstruction that came and went. He therefore deemed it unwise to do a cholecystectomy and decided to do a cholecystenterostomy. The duodenum, however, was so matted with adhesions, and the gall-bladder was contracted to such an extent, that he did not think he could make the anastomosis with safety. He therefore utilized the hepatic flexure, and made a Murphy-button anastomosis with gauze drainage. There was no untoward symptom; a little bile came out after the gauze, when it was removed on the third day, but none thereafter, the drainage-tract closed quickly. The jaundice faded, the urine cleared up, and the patient had two normal bowel actions a day, whereas he had been previously taking purgatives daily. He went home at the end of two weeks with a clear complexion, and a gain in weight, and has had no trouble since, but the button has not passed. McGuire reports a button retained over a year in cholecystenterostomy, but Treves has never had one remain in the gall-bladder.

In the discussion DR. F. W. MCRAE of Atlanta narrated a case operated upon a few months ago in which a diagnosis of cholecystitis was made. At the operation an unusual condition of affairs was found. Instead of a distended gall-bladder, he found enlargement of the liver, with great distention of a cavity in this organ, hard and nodular to the feel, and occupying this cavity and some small pockets in various directions in the liver were fifty-eight stones, which he exhibited. The adhesions were extensive, but no pus was found.

DR. J. G. EARNEST of Atlanta directed attention to the symptom jaundice, saying that it does not appear unless there is obstruction of the common duct. Simple obstruction of the cystic duct does not necessarily produce jaundice. In two or three cases in which he has found the gall-bladder filled with inspissated mucus and complete obstruction of the cystic duct, but no obstruction of the common duct, there was no jaundice, while in other instances of common duct obstruction, jaundice was present.

DR. HUGH M. TAYLOR of Richmond, Va., recalled a case which was diagnosticated at first as cholecystitis. The patient had been jaundiced for six weeks. The abdomen was opened, and on incising the gall-bladder and removing a stone from it, he found no obstruction of either the cystic or common duct. He did a cholecystostomy, drained the gall-bladder, but the patient did not recover health. Two months later he reopened the abdomen, and, after a very careful examination, found malignant disease of the head of the pancreas sufficient to press upon the common duct and produce jaundice.

DR. MANNING SIMONS of Charleston, S. C., reported a case in which he removed the whole gall bladder, and said, after a careful search of the literature at his command, he could find reports of only twenty cases. The tumor in his case presented just below the ninth rib as large as a goose egg. An exploratory operation was made, and the tumor was found to be the gall-bladder. The gall-bladder was removed because its walls were greatly thickened and pus had disseminated itself throughout its walls. He believes that if the gall-bladder had not been removed at that time, and promptly, there would have been extravasation of pus into the abdominal cavity. Three gall-stones were found. There was very little jaundice present.

DR. A. M. CARTLEDGE of Louisville, spoke of the cholemic cases, and said that in the use of the normal saline solution, employed subcutaneously or per rectum, for ten days, two weeks, or, in bad cases, three weeks, before operative interference, surgeons had one of the most valuable means of overcoming cholemia in patients with gall-stones.

DR. WILLIAM P. NICHOLSON of Atlanta followed with a paper, entitled

INFLAMMATION OF MECKEL'S DIVERTICULUM WITH RESULTING GANGRENE OF THE INTESTINE SIMULATING APPENDICITIS.

The pathological conditions arising from the diverticulum have been in most cases due to portions of the intestine being entrapped within the encircling cord where the diverticulum has existed in this form; while in some instances there has been an acute inflammation of the pervious tube that has caused adhesions and resulting obstruction. Again, the inflammation seems to have extended to the intestinal tube causing paresis of the bowel, especially simulating the later stages of appendicitis. In a few cases the symptoms and signs have been so much like inflammation of the appendix that a diagnosis has not been possible.

The author reported an interesting and instructive case, and mentioned briefly other cases he had found in consulting the literature. He also reported a case of successful implantation of an artificial testicle.

DR. T. J. CROFFORD of Memphis reported

TWO CASES OF INTRALIGAMENTOUS CYSTS.

CASE I.—Miss T., aged fifty, presented herself with an abdominal tumor July 1, 1899. A few days later the abdomen was opened. The tumor was found to be an intraligamentous cyst. Both ovarian arteries were ligated; the uterine artery was ligated upon the healthy side at as low a level as the internal os. The uterus was cut across; the uterine artery secured upon the tumor side and the enucleation of the tumor proceeded with. The loss of blood was considerable, although the enucleation was done rapidly. Several arteries in the broad ligament required ligation, and one or two deep down in the pelvis needed to be secured before hemorrhage was under control. The cavity was obliterated as much as possible by suturing together the two layers of the ligament. The woman recovered.

CASE II.—Mrs. S., aged forty-two, presented herself with an abdominal tumor October 31, 1899. During the month of June last she experienced an attack of acute peritonitis which came near terminating her life. The acuteness of the attack subsided, but a chronic peritonitis has existed ever since. Abdominal section was made November 6th. There were found two tumors, one on each side, developed between the layers of the broad ligaments. The ovarian arteries were secured near the brim of the pelvis. The tumors, which were not of very large size, were separated from the uterus as far down as the operator dared, and the uterine arteries were secured as low as possible after emptying the cysts. The hemorrhage was alarming at every attempt at enucleation upon all sides. The larger vessels in the broad ligaments and walls of the cysts, several in number, were, therefore, ligated. The upper portion of the sacs was trimmed off and covered with peritoneum. After the oozing had stopped the abdomen was closed without drainage. The patient has had an uninterrupted convalescence and has returned to her home.

The essayist said that Dr. Rufus B. Hall of Cincinnati had proposed the method of ligating both ovarian arteries and the uterine artery on the healthy side. The uterus was next amputated on a level with the internal os; the uterine artery on the tumor side was not secured, when he could peel out the cyst from between the layers of the broad ligament with a bloodless result. While he did not wish to detract from the merits of this achievement, yet the method is not to be implicitly relied upon as it will not control hemorrhage in all cases to a safe degree; that in some instances there will be found other vessels requiring ligation before the hemorrhage can be controlled within the bounds of safety. Some tumors of the broad ligament can be peeled out without hemorrhage; others will be attended with considerable loss of blood.

THE PRESIDENT'S ADDRESS.

This was delivered by DR. JOSEPH TABER JOHNSON of Washington, D. C. He touched on general subjects pertaining to the work and growth of the association. The Southern part of our country had furnished many noted surgeons and gynecologists to the medical profession, hence the name of the association derived greater appropriateness and significance from this fact. McDowell, Eve, Dudley, Sims, Thomas, Battey, and Emmet were referred to. The best gynecologists are now the best surgeons as far as they go. In abdominal, pelvic, and genital surgery, few general surgeons equal, and none surpass them. Their field of work was more narrow but none the less perfect and important on that account. While many gynecologists might take exception to such an absorption of their specialty, the gradual expansion of their work to the female pelvis gives the important argument for such an occurrence in the not distant future. It is not difficult to remember when gynecology was limited altogether to vaginal and pelvic work. Now, there are very few gynecologists who were not operating upon any tumor between the diaphragm and the vulva. The gynecologists attack ulcers and abscesses of the stomach and anastomosed that organ with the intestine. They did all surgery of the ureter and kidney, the liver and gall-bladder, of the intestines, the spleen and pancreas. They operate for appendicitis and for all the varieties of hernia, and did the surgery of the bladder, the rectum, and the mammary gland.

There was no afternoon session of the second day. The members and guests took the steamer "Warren" and rode to the sugar plantation "Stanton, owned by Milliken and Ruttledge, and inspected it.

SECOND DAY—EVENING SESSION.

DR. HUGH M. TAYLOR of Richmond, Va., read a paper on

EXPERIENCE IN OPERATIONS FOR TYPHOID PERFORATION.

It is claimed that one-third of the deaths from typhoid fever are due to perforation. Typhoid perforation is credited with a mortality of 16,660 each year in the United States. The specialist in surgery appreciates what surgery can do and has done in the treatment of typhoid perforations. The general practitioner, in whose hands these cases annually first fall, is not so well informed, and he believes the Association should express itself in no uncertain sound. It is claimed, too, that one-fifth of the deaths from typhoid fever are due to hemorrhage. This being so, it would seem just as unsurgical to let a typhoid patient die without an effort to save his life as it would be in the case of profuse hemorrhage from a gastric or duodenal ulcer, or even a ruptured tubal gestation. The author reported five cases, with one recovery from operation.

Less than 200 cases have now been operated upon. When one recalled the thousands of cases annually occurring, the need for cooperative study is apparent. Nothing short of a moribund condition of the patient should warrant surgeons in abandoning a case as hopeless. The key to success is early operation. More than one-fourth of the cases operated on have been saved by early surgical intervention. He believes that surgeons should be able to save more than 33⅓ per cent. by a time operation.

DR. F. W. MCRAE of Atlanta, Ga., reported some

interesting cases of abdominal surgery. The first case was one in which he operated for a pancreatic cyst; the second for hepatic calculi; the third for fecal fistulæ, and in the fourth case he did a combined appendectomy and nephrorrhaphy.

LITHOLAPAXY.

DR. GEORGE S. BROWN of Birmingham, Ala., read a paper with this title. A very limited experience with the operation of litholapaxy has led him to believe that it is being unwisely, although not altogether unreasonably, neglected. The most important cause for this neglect was that perhaps cutting operations, particularly the suprapubic, are very easy to do, and the results are very satisfactory. The author quoted the statistics of the different methods of operating for stone in the bladder, and reported cases in which he had resorted to litholapaxy with good results. The majority of stones met with in practice in this country can be removed with the lithotrite in the hands of an ordinarily careful surgeon, and that while it is not an operation to be undertaken by the general practitioner, no operating-room should be without one; suffering and time spent in bed are almost entirely eliminated, and the mortality is very much lower than that for either of the cutting operations.

DECEMBER 7TH—THIRD DAY—MORNING SESSION.

DR. E. D. FENNER of New Orleans, La., reported fifteen cases of spinal injuries treated at the Louisiana Charity Hospital.

DR. GEORGE H. NOBLE of Atlanta, Ga., described the modification of an operation for cystocele. He also reported a case of seventeen years' congenital nocturnal incontinence of urine and one of pregnancy in a uterus bicornus.

DR. I. L. WATKINS of Montgomery, Ala., presented a paper on "The Treatment of Retrodisplacements of the Uterus."

The following officers were elected: President, Dr. A. M. Cartledge, Louisville, Ky.; vice-presidents, Dr. Manning Simons, of Charleston, S. C., and Dr. W. P. Nicholson, of Atlanta, Ga.; secretary, Dr. N. E. B Davis, of Birmingham, Ala.; treasurer, Dr. W. D. Haggard, Jr., of Nashville, Tenn. Atlanta, Ga., was selected as the place for holding the next annual meeting. The time for meeting was the second Tuesday in November, 1900.

THE NEW YORK COUNTY MEDICAL ASSOCIATION.

Regular Meeting, Held November 20, 1899.

DR. F. HOLME WIGGIN, President, in the Chair.

DR. EMIL MAYER of New York City read a paper, entitled

THE TONSILS AS PORTALS OF INFECTION.

In his remarks he called attention to the fact that certain forms of infectious disease follow closely on tonsillar infection, the same micrococci existing in the former as in the latter, thus proving their tonsillar origin. Some of these facts are well known, while some others being but recently promulgated are not, and have, therefore, received but scant consideration.

The importance of a study of these conditions becomes very necessary in that most important field, preventive medicine. The pathology of the tonsil in disease was discussed, and the work of Hodenpyl, Patterson, Goodale, Cobb, and others mentioned. A result of these studies was reached in the conclusion that acute tonsillitis furnishes an entrance for bacteria into the system through the tonsils, and that this belief explains a pericarditis, for instance, and makes a belief in its rheumatic origin unnecessary.

A number of authorities were quoted showing conclusively the tonsillar origin of rheumatism. Other conditions noted to have followed directly after anginas were albuminuria, erythema, urticaria, purpura, erysipelas, orchitis, and oophoritis, pleuropneumonia, strabismus, paraplegia, and osteo-myelitis.

Angina pectoris has been reported to have followed tonsillar disease in four cases. Phlebitis of the leg, pneumonia, and purulent pleurisy are recorded as following disease of the tonsil. The tonsils have long been suspected as being the points of infection in tuberculosis, while it was well known that otitis media with its mastoid and intracranial complications followed tonsillar disease. It has been shown quite lately that endocarditis must be added to the list.

The case reported by Charrin was cited, that of a young man of eighteen years, who died of general pyemia consequent to tonsillar affection. The autopsy showed bronchopneumonia and deposits on the tip of the pulmonary valves. Staphylococcus aureus was found there and also on the white tonsillar exudate. Other cases were cited from the literature, including the five reported by F. A. Packard of Philadelphia To these the writer was enabled to add another which was seen by himself, for the history and diagnosis of which he was indebted to Dr. Jacob Fuhs of Brooklyn. In this case hemichorea subsequently developed. Recovery was complete.

Granting that the etiologic factors of some of the infectious diseases have been established, it becomes a duty to take steps tending to prevent such infection. Vigorous treatment with rest in bed was advised for the follicular tonsillitis, while the abortive treatment should be attempted in the cases of peritonsillitis. This, the writer said, he had been able to do so frequently that he declared it to be an established clinical fact if the patient was seen early. The remedy consisted of:

℞	Morph. sulph. . . .	gm. 0.06
	Tr. veratr. virid. . . .	4.0
	Aq.	126.0.

M. S. Teaspoonful every hour for three hours; then once in three hours.

In twenty-four hours all symptoms are gone. If not, the remedy is no longer efficacious, and the tedious wait of ten days of agony must be undergone.

After these anginas have subsided, a very careful examination of the fauces should be made, and every bit of tonsillar tissue removed either with the Farlow gouge or the galvanocautery.

The ordinary tonsillotomy was not sufficient.

The strictest attention to hygiene of the mouth should be enjoined even after thorough ablation of the tonsil. Under no circumstances whatever should any operative procedures be undertaken while an acute process is going on.

The conclusions arrived at were:

1. Infection arises in the tonsil.

2. Tonsillar affections are frequently serious in their sequelæ, and every step to prevent recurrent attacks should be taken.

3. The existing tonsillar disease should be energetically treated.

4. Careful examinations and treatment are absolutely essential in the interim.

5. Following anginas, the heart and other organs should be examined from time to time.

DISCUSSION.

DR. ISAAC ADLER opened the discussion. He said that he was indebted to Dr. Mayer for presenting this subject, as it was one in which he was especially interested. Regarding the pleuritic affection, this, he said, was indubitably proven. A rheumatic diathesis could not be regarded as a fact since the disease was the result of an acute infection.

He was not prepared to accept the pneumonia and angina pectoris cases as fully proven, although the pleurisy cases certainly were. Regarding the case of endocarditis cited, it seemed to him from the physical signs reported and absence of temperature that it was one of myocarditis. This was important, for it would explain much that was hitherto misunderstood if it could be explained that a myocarditis was as apt to follow a tonsillar angina of a non diphtheritic nature as it so frequently did in diphtheria.

DR. F. A. PACKARD of Philadelphia spoke of five cases he had previously reported, and added two more to the list. It was noteworthy that the patients had had no cardiac affection previous to the tonsillar attack. Endocarditis supervening, valvular lesions occurred in all, and have remained.

DR. F. J. QUINLAN endorsed the views of the reader of the paper, and dwelt particularly on the aural and cerebral complications that follow tonsillar diseases.

DR. S. S. JONES said that he felt that an explanation of the possible cause for the sudden deaths that followed a simple tonsillar affection had been offered.

DR. MAYER, in closing, said that he was disposed to agree with Dr. Adler with reference to the case he had reported as being myocardial rather than endocardial, not only because of absence of fever, but because of the subsequent cure of this case, for he noted that every one of Dr. Packard's cases still had their valvular lesions, which is so true of endocardial inflammations, and this would also explain the point raised by Dr. Jones

He failed to agree with the suggestion that the trouble was in the nasopharynx, for it was contrary to every observation, and, indeed, it was only possible to view this question from the standpoint of the general practitioner.

He wished to be clearly understood as referring to tonsils subject to disease only, but when these are frequently the seat of disease no simple tonsillotomy was sufficient, but complete extirpation is required.

REVIEWS.

PYORRHEA ALVEOLARIS. By JOHN FITZGERALD, L.D.S., Dental Surgeon to the Italian Hospital and to the National Hospital for Diseases of the Heart and Paralysis, Soho Square, London: The Medical Publishing Co., Limited, 1899.

A COLLECTION of articles previously recorded in the *Clinical Journal* makes up this small brochure. It gives a fairly complete survey of this subject so familiar to the dentist, the importance of which the author endeavors to bring home to the physician by emphasizing its clinical relation to some diseases of the stomach. Its far greater surgical import has been neglected inasmuch as there is no mention of its relationship to inflammation of the inferior maxilla and cervical glandular enlargements. The American literature is extensively quoted.

BACTERIOLOGY IN MEDICINE AND SURGERY. A Practical Manual for Physicians, Health Officers and Students. By WM. HALLOCK PARK, M.D., Associate Professor of Bacteriology and Hygiene, University and Bellevue Hospital Medical College, and Assistant Director of the Research Laboratories of the Department of Health, City of New York. Assisted by A. R. GUERARD, M.D., Assistant Bacteriologist, Department of Health, City of New York. Illustrated with 87 engravings and 2 colored plates. New York and Philadelphia: Lea Brothers & Co., 1899.

WE have seen no work of recent time, which in small compass, has so thoroughly covered every-day practical bacteriology as does this manual of 683 pages with 36 chapters and an appendix. Eighteen of the chapters are concerned with general bacteriology; historical sketch, general morphologic characters, chemical composition, vital phenomena, relation to disease, immunity and its theories, infection, effects of physical agents on bacteria, temperature, chemical agents, practical disinfection of houses, persons, instruments, foods for adults and infants, preparation and technic of staining, cultivation of bacteria and media, animal experimentation, human investigations, bacteriological examination of water and air and the classification of bacteria are the subjects treated in these 18 chapters. The succeeding chapters describe, especially from the hygienic or medical, rather from the more technical bacteriological standpoint, the many important bacteria of disease, the bacillus tuberculosis and its allies, influenza, diphtheria, tetanus, and typhoid bacilli, the baccillus coli communis, the micro-organisms of pneumonia, abscess production, meningitis, anthrax, glanders, bubonic plague, and cholera.

To these there is added an appendix of four chapters in which there is given a brief description of a few representative pathogenic micro-organisms which are not usually grouped with the bacteria. These are actinomycosis, favus and ringworm; the plasmodium of malaria, and other animal parasites, amebæ, the micro-organisms of smallpox and cowpox and a general discussion of hydrophobia. In addition to the ordinary index there is an extremely convenient index of infectious diseases with the bacteria found in them.

For the practical purposes of the doctor this volume will be found extremely useful. The author has escaped the prolixity of superflous compilation on the one hand and the barrenness of direct copying from other text-books on the other and has crystallized in a simple, forceful manner a great amount of his own wide experience. We believe that the book can be heartily commended to those for whom it was written, the student, health-officer, and practitioner.

THE MEDICAL NEWS VISITING LIST FOR 1900. Weekly (dated, for 30 patients); Monthly (undated, for 120 patients per month); Perpetual (undated, for 30 patients weekly per year); and Perpetual (undated, for 60 patients weekly per year). New York: Lea Brothers & Co., 1899.

THIS well-known visiting list has appeared. It is, perhaps, a little more attractive than usual, by reason of its alligator-skin cover, which renders it durable as well as enhances its appearance. It includes formulæ, antidotes for poisons, pages for general memoranda, obstetric engagements, deaths, vaccinations and accounts. For the purpose, we know no visiting list which will better suit the purposes of physicians.

THERAPEUTIC HINTS.

Local Massage in Exophthalmic Goiter.—ZABLUDOWSK, of Berlin has been able by means of a system of massage to effect decided amelioration of the chief symptoms of this disease, especially when the goiter was of the soft pulsating variety. He begins by kneading the gland up and down and from side to side, using both hands as if squeezing a sponge. This is well borne if only part of the gland is treated at a time. If the goiter is very sensitive the massage is carried out by one hand, while the other is used to percuss the spine, this procedure having a good effect on the tachycardia. In addition, Zabludowski practises intermittent and vibratory percussion of certain nerves at the most accessible part of their course the pneumogastric, chief trunk of the sympathetic, occipital, cervical, and the intercostal. He recommends, further, passive movements of the whole body, the muscles being weak as a result of poor nutrition. In from four to six weeks marked improvement is evident.

Treatment of Night-sweats of Phthisis by Formaldehyd.—The good results of treatment by this drug seen in cases of hyperidrosis and bromidrosis caused HIRSCHFELD of Berlin to try its action for phthisical sweats. He now recommends it highly. Because of its power of penetrating the skin he uses an alcoholic solution, as follows:

℞ Formaldehyd, forty per cent. } aa. . ℥ ii.
Spiritus abs. }

M. Sig. External use. Apply on a swab.

Only one part of the body is treated at one sitting; the shoulders and arms, for instance, on the first day, the lower extremities on the day following, and the trunk on the third. From 1 to 2½ drams of the solution is used each time. By following this method toxic absorption and excessive irritation of the ocular and respiratory mucous membrane are alike avoided. If, nevertheless, a fit of coughing should be provoked, the application should be made very rapidly and the part covered at once. Cotton wet with spirits of turpentine can be held in front of the nose and mouth of a sensitive patient. The treatment is not painful, only a momentary burning sensation being produced. Newly formed epidermis, excoriations, and mucous surfaces should, of course, be avoided. The effect of the application lasts from five days to a month, as a rule from one to two weeks. The sweats cease meanwhile, and as no injury is caused by the treatment it can be resumed whenever necessary.

Mercurial Ointment for Malignant Pustule.—When situated on an eyelid or lip, for instance, it is very undesirable to treat the pustule by injections, cautery, or excision on account of the deforming cicatrix which would result. REINA (Italy) has in such cases effected perfect cures by applications of mercurial ointment, sometimes first touching the pustule with a few drops of nitric acid. Recovery was rapid and the scar hardly perceptible. He regards the ointment as superior to the cautery or injections of carbolic in its influence on the disease process.

For Psoriasis.—

The following formula is said to be an improvement on that of HELMURICH in regard to consistency, and because, unlike the latter, it does not darken the skin:

℞ Sulohuris sublim. . . . ℥ i
Potassii carb. . . . . ℥ ss
Aq. dest. . . . . ℥ ii
Lanolini anhydr. . . . . ℥ ss
Vaselini . . . . . ℥ ii.

Mix the sulphur with the lanolin. Then add the vaselin. Dissolve the carbonate of potassium in the water and stir the solution, a little at a time, into the ointment.

Pomades Made with Yolk of Egg.—UNNA (Hamburg) recommends this form of pomade, since it dries quickly and forms an adherent covering, and is a veritable base for any of the usual medicaments—ichthyol, sulphur, turpentine, starch, etc., which may be added in the proportion of ten per cent. To prevent decomposition one per cent. balsam of Peru should be added. The pomade is especially serviceable for cases of eczema, acne, and scabies.

℞ Yolk of egg . . . . 2 parts
Olive oil . . . . . 3 parts.

Rub together as if for a mayonnaise.

THE MEDICAL NEWS.
A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXV. NEW YORK, SATURDAY, DECEMBER 30, 1899. NO. 27.

ORIGINAL ARTICLES.

SPLENECTOMY, WITH A REPORT OF TWO CASES.

BY J. WESLEY BOVÉE, M.D.,
OF WASHINGTON, D. C.;
CLINICAL PROFESSOR OF GYNECOLOGY IN THE COLUMBIAN UNIVERSITY; GYNECOLOGICAL SURGEON TO THE COLUMBIA AND PROVIDENCE HOSPITALS.

SPLENECTOMY, an operation the early history of which is very much shrouded in doubt, was probably first performed by Zanarelli, a Neapolitan, in 1549. Fioravanti is said to have performed it about the same time, and Viard, a French surgeon, is credited with having done the operation in 1581, and Matthias in 1678. The next two cases are reported as having been done by Ferrerius in 1711, and O'Brien in 1814. Pernet, and a few other medical historians believe O'Brien's operation was the first in which the spleen was extirpated from the living human body. From that time to 1867 reports of a few cases, nearly all resulting fatally, are scattered through medical literature. In this latter year Pean successfully removed an enlarged and cystic spleen, thus really introducing the operation into modern surgery. Since that time it has been frequently performed, the number of operations has run into the hundreds, and the mortality-rate has markedly decreased.

As this organ was until recently very little understood, it has been subjected to much experimentation. Its fickleness as to its existence in certain individuals has still further enhanced its mystery, as has its slow development in early life and its disappearance in adolescence. Martin and a number of other writers have reported absence of the organ without even a splenic artery being given off from the celiac axis, while others have noted its duplication. Thus Cheselden has reported the presence of two to three spleens in three instances, and Albrecht of Vienna reports on at least five hundred spleens which varied in size from that of a pin-head to a walnut. In many of these cases of splenic duplication the structure of the supplementary bodies was demonstrated by the microscope. Numbers of the supplementary spleens are occasionally found in the usual location of the spleen, each being supplied by its branch of the splenic artery, and vein. This is probably due to a lack of development. In this connection the reports of Tedeschi and Masoin, based upon experiments on animals are quite interesting. The former claims that the spleen is reformed after extirpation, and the latter that by breeding from splenectomied rabbits the spleen can be made to congenitally atrophy. A number of cases have been reported in which the spleen was markedly atrophied.

This organ is supposed to be the source of origin of leucocytes and the graveyard of the red blood-cells. Its necessity for the maintenance of life and health, as may be inferred from the above, is clearly disproven by the fact that the lymphatic glands and bone-marrow can take up its work. This compensatory function, however, is not rapidly assumed in all cases. Experimental splenectomy on animals has shown that it occurs more rapidly and with less general disturbance in young animals, and it has been noticed that children have been much less affected by removal of the normal spleen than have adults. Injuries to this organ requiring its removal have been sufficiently frequent to afford opportunities for the positive determination of this fact. Tizzoni, who has demonstrated it, attributes the slowness of this compensation to the slow return from the inertia of the other hematopoietic organs. No characteristic symptoms accompany splenectomy in children, while in adults a serious train of them follows removal of even the normal spleen. In adult man these post-operative symptoms are about as follows: Increased frequency of pulse, fainting attacks with great pallor of the skin, a daily rising temperature, progressive weakness and loss of weight, great anemia, withered and sallow appearance of the face, headache, drowsiness, voracity, thirst, diminished or increased urinary excretion, griping pain in the abdomen and pain and tenderness of the long bones. Certain characteristic changes occur in the blood and an enlargement of the lymphatic glands is seen. These symptoms appear a few days after the operation, are severe for two or three weeks and then slowly disappear.

In children, who practically have none of these symptoms, probably owing to their red bone-marrow at once assuming the splenic functions, hunger is marked and the quantity of urine at first is diminished. In adults there is great thirst and usually increased urinary excretion. The pain and tenderness of the long bones is probably due to the changes going on in the bone-marrow incident to the establishment here of the assumed functions. Experiments on animals have shown that this change be-

gins at the periphery of the medulla and extends progressively inward and consists of the absorption of the fat of the yellow marrow and its replacement by red bone-marrow. Emilianow, from his observations on dogs, suggests that the lymphatic glands assume the functions of the Malpighian corpuscles and that the bone-marrow acts for the remainder of the splenic pulp. Reigner, in 1892, removed a ruptured spleen from a boy fourteen years of age, and later was obliged to amputate the leg of his patient. A careful examination of the bone-marrow of this extremity permitted him to positively demonstrate the changes it had undergone. The griping abdominal pains are said by Ballance and others to be due to enlargement of the lymphatic glands of that region. In Reigner's case a large ventral hernia developed, through which, ten months after splenectomy, he was enabled to feel the enlarged lymphatic glands. Mosler and Tizzoni have demonstrated that in splenectomied dogs the mesenteric glands are enlarged and on section are red with white spots like Malpighian corpuscles. They also report finding throughout the mesentery small rounded masses of lymphoid cells closely resembling spleen tissue. These are probably similar to the many supplementary spleens found in the mesentery in cases where the spleen is absent or extremely diminutive. The blood changes following removal of the normal spleen in the adult man or animal, consist of a rapid diminution in the proportionate number of the red corpuscles and an increase in the number of leucocytes with marked lowering of the percentage of hemoglobin In the course of three or four weeks following operation, a reverse of these changes begins, and in from two to three weeks more the blood shows normal conditions.

Indications for Operations. — Among the conditions recognized as indications for splenectomy are, enlargement of the organ due to paludal, tubercular, or idiopathic causes, malignant disease, axial rotation, wandering of the organ, echinococcus and other cysts, chronic congestion, amyloid disease, and rupture. The operation has been done a number of times for extreme enlargement of this organ incident to leucocytosis, but nearly all resulted fatally. In simple hypertrophy great inconvenience and distress results from the presence of the tumor. Pressure on other organs, dragging on its pedicle, and the extreme sense of weight are the principal reasons for its removal In the malarial form of hypertrophy we find that there exists, in addition to other conditions mentioned, a paludal intoxication that can not be avoided until the growth is removed. This has been demonstrated in a number of cases by blood examinations made before and after operation. The marked rise in number of red cells and corresponding rapid lowering of the number of leucocytes with rise of hemoglobin percentage seem to demonstrate the immediate effect of the operation on the blood conditions, and are in marked contrast to the conditions following removal of the normal spleen. In Hartmann's case the blood estimated the day before operation was as follows: Number of red cells 3,400,000, leucocytes 7000, hemoglobin 100 per cent. Eight days after operation the number of red cells had increased to 3,800,000, the leucocytes had diminished to 4250, and the amount of hemoglobin had fallen to 85 per cent. This shows particularly the marked increase in the number of red cells. Jonnesco and Vanverts were so appreciative of this fact that they recommend splenectomy as a cure for malarial poisoning.

In tubercular enlargement of the spleen the same rules hold good regarding extirpation. The wandering spleen probably appeals most strongly for extirpation. It is by no means easy to understand how this organ, suspended to the diaphragm by peritoneum, to the pancreas by blood vessels and to the stomach by the gastrosplenic omentum could be so far displaced as to reach the pelvis. It is probably due to unusual strain on its pedicle, such as follows parturition, for it nearly always occurs in women who have borne children. The displacement of the organ may cause engorgement, atrophy, or rotation on its axis. The engorgement is usually due to the dependent position of the organ. Atrophy, resulting from its displacement, is also due to interference with its circulation. Such displacement may have a deleterious effect on other organs. Dilatation of the stomach, fermentation of food, and vomiting are common symptoms and jaundice as a result of angulation of the bile ducts is also mentioned. Adhesions to various parts of the intestine may cause intestinal obstruction. The tail of the pancreas being in close proximity to this organ has been incorporated in its pedicle. It has even caused retroflexion of the uterus with prolapse of that organ, and of the vagina and bladder. This condition endangers life through liability to rupture of, or the formation of an abscess in, the spleen, to intestinal obstruction or to rupture of the stomach or the duodenum. In primary malignant disease of the spleen early operation is indicated. But thus far splenectomy for this condition has not proven satisfactory. Hartley found, of six patients operated on, one died immediately after, three recovered from operation but died of recurrence of the disease, and two, in which the tumor was very small, were still alive. In the last two cases operation was evidently performed early. It is very doubtful whether symp-

toms of malignant disease of the spleen will be recognized sufficiently early to allow of extirpation and eradication.

In axial rotation the formation of adhesions to other organs, the danger of infarction, gangrene, and rupture, will call for removal of the organ Infarction usually results from this condition. For cysts of various kinds splenectomy is particularly indicated. The operation of simple puncture of these cysts has a mortality of eighteen per cent , while splenectomy has a death-rate of but seventeen per cent. Rupture of the spleen is one of the most important indications for operation. It is usually due to injury and may occur in the normal or in the diseased organ. In the various hypertrophies we have a strong predisposing cause in the presence of a thin walled tumor filling a considerable portion of the abdominal cavity and protruding to a considerable extent. In some cases the rupture has occurred spontaneously. The great danger in rupture of the spleen is the severe hemorrhage that usually accompanies it, which, while often fatal, does not cause death as often as might be expected. This is probably due to the exceptional coagulability of the blood in the veins of the normal spleen, but in diseased conditions this is not present. In Reigner's case the lower half of the spleen lay loose in the abdominal cavity, and the operation was successfully done the following day. The rhythmical contraction and expansion of the spleen tend to loosen the blood-clots and promote additional hemorrhage, making excision imperative. It is important in rupture of the normal spleen that excision should be done about the second day. In diseased conditions of the organ this rule does not equally apply, as the tendency to hemorrhage is greater, owing to the blood conditions and the larger size of the vessels. At the time of injury severe shock occurs as the result of blow, and the escape of large quantities of blood into the peritoneal cavity. This condition is recognized from the character and locality of the injury, the clinical evidence of internal hemorrhage, the pronounced shock and the large area of dulness in the left flank. The dulness in this region is due to accumulation of blood-clot which does not change its position by change of the patient's position and is considered pathognomonic. It does not occur in intra abdominal hemorrhage from other organs.

Contraindications.—It is probably more important to recognize the conditions which contraindicate splenectomy than to be conversant with those requiring it. When the tumor is extremely large, pressing on the diaphragm, liver, and even the uterus, the prospect of removal of the spleen is exceedingly slight. The size of the organ is somewhat prodigious, reaching thirty to forty pounds in weight. The adhesions formed between the spleen and other organs or structures are sometimes very extensive, and owing to the vascular character of the spleen they are usually liberally supplied with blood-vessels. The traumatism incident to division of such extensive adhesions is very great, and owing to their vascularity severe hemorrhage and very slow progress in the operation are usual. The mortality-rate of splenectomy when such extensive adhesions are present is very much higher than when they are absent. Vanverts found that in 39 cases of enlargement with extensive adhesions, 28 died, while in 35 cases without adhesions only 2 died. Leucocythemia is probably the most dangerous condition that can confront the surgeon in splenectomy. Of over 100 operations with this complicating condition but 3 have been successful, and in these the degree of leucocythemia was very moderate. Warbasse says that when the proportion of white to red blood-cells falls below one to fifty the operation should not be done, and, indeed, we think this proportion is far too low. Profound cachexia is a very strong contraindication to the operation. In short, splenectomy should never be done except under the most favorable circumstances, unless immediate death threatens.

Splenopexia.—This operation has been strongly advocated by Bardenheuer, Stierlin, Rydigier, Hartmann, Tikoff, and Heydenreich. Stierlin would employ it when the organ is not more than three times its normal size. The operation is difficult because of the thinness of the capsule and the great vascularity of the organ. Rydigier places it in an extraperitoneal pocket, formed by splitting the parietal peritoneum transversely and dissecting back an upper and lower flap. He then partly closes over it the peritoneal incision, taking one to three stitches in the gastrosplenic epiploon. Extra stitches are placed if thought necessary. The methods of Bardenheuer and Tikoff are slight modifications of this. It would seem that this operation has a very narrow field of application. If the spleen is entirely normal in every respect its fixation at some point, not necessarily at its normal site, may be done, except when it is floating about in the peritoneal cavity and has formed no adhesions to other structures. In my judgment this is the only class in which the operation is applicable. It must be remembered that this operation requires the opening of the peritoneal cavity as well as splenectomy, and that the spleen is not by any means a necessary organ. Therefore, if it be complicated by a diseased condition or anything else, splenectomy is the preferable operation. Under such circumstances its mortality-

rate would not be higher than that of simple ovariotomy.

Symptoms.—The symptomatology of the various conditions calling for splenectomy is necessarily a symptom complex. Yet the symptoms are nearly always referable to the location of the organ. In great enlargement, interfering with the functions of other organs, the symptoms are not clear as they often emphasize the resulting ailments rather than the splenic condition. A wandering spleen being found in any part of the abdominal cavity and very often adherent to other organs will frequently give rise to symptoms of derangement of the other organs affected by the presence of the spleen. In ruptured spleen the symptoms are of profound shock and internal hemorrhage. These are usually associated with marked dulness in the left side, with a history of injury and perhaps the presence of a tumor in that region. In malarial enlargement a history of malarial intoxication, with or without chills and fever, is procured. Localized pain, mild or severe, is nearly always present and marked cachexia is often noticed. In tubercular spleen the differential symptoms are not always at hand and the same may be said of malignant disease in its early stages.

The condition of the blood is of the greatest importance. Examination of the blood should, if possible, be made before operation a sufficient number of times to determine its exact condition, and whether it indicates that the patient is improving or getting worse. After operation it should also be studied. This will furnish data for the future conduct of the case as well as to determine the prognosis. If the organ is sufficiently diseased to interfere with its function the subsequent blood changes will be much less than when the removed organ is normal in structure. In leucocythemia the blood examination readily demonstrates the condition and upon the microscopical diagnosis alone is placed nearly the entire responsibility of deciding between operation and nonintervention. In malarial enlargement such examination is not to be wholly relied upon, as conclusive evidence of the disease so far as yet known is not always to be found. In a number of cases of malarial poisoning examinations of the peripheral blood failed to demonstrate the cause of the disease, while positive evidence was found in the spleen.

Complications.—An important complication of splenectomy is variation from the normal blood conditions. As before mentioned leucocythemia is the worst complication. Marked anemia and other well known pathologic conditions of the blood are causes of additional mortality in this operation. Extensive adhesions very materially complicate the operation, being very liable to sacrifice the life of the patient. The large size of the organ renders it very hazardous. Disease of other organs, especially of the liver, often give trouble, if indeed they do not sap the life of the patient at the time of operation or later. Pregnancy has in three cases, those or Rakhmanoff, Spencer, Wells and Savor, been present, and in the latter two, births at full term are reported.

Diagnosis.—The diagnosis of a splenic tumor is not usually difficult. No matter how large the tumor may be, unless cystic, the characteristic notch or notches can be felt in the right border of the growth and the larger the tumor the larger and more distinct will be the notch. The consistency of the organ, except in marked pathologic changes, is characteristic of the spleen. Then its position with partial fixation on the left side leave little doubt. Wandering spleen is seldom diagnosed before the abdomen is opened and may be confounded with a uterine fibroid, an ovarian tumor or a movable or enlarged kidney. Rupture of the spleen is easily diagnosed from the symptoms already detailed.

Technic.—But little need be said concerning this to abdominal surgeons. Yet one important point is worthy of mention, and that is the ligation and division of the gastrosplenic ligament before dealing with the large blood-vessels. This materially aids the operator as it loosens the organ, and permits of changes in its position. This is a matter of great convenience in placing ligatures on the vessels and prevents dragging on the diaphragm and on the pedicle of the severed vessels. Every operator emphasizes the necessity of ligating the blood vessels separately and then placing a mass ligature below these on the pedicle. These precautions are to ensure against both primary and secondary hemorrhage. But if the pedicle be dragged on, the danger of loosening the ligatures must be apparent to all, and such dragging is inevitable in all cases of enlarged spleen when normally located, unless this ligament be first divided and the vessels ligated last. The artery should if possible be first ligated to prevent an extra amount of blood being forced into the organ after the return flow is cut off. When we consider the distensibility of the organ and its capacity for blood this matter will not seem of slight importance.

Results.—Hartley collected reports of 126 cases of splenectomy, performed for conditions other than leucocythemia from 1896 to the date of his paper in 1898, with a mortality-rate of 20.5 per cent. I find recorded, since his paper appeared, accounts of 73 cases with 10 deaths, a mortality-rate of 13.7 per cent. Leucocythemia being a condition so absolutely unreconcilable with splenectomy that, not-

withstanding one of mine was of that character, I made no attempt to collect reports of such cases if any are recorded during the past eighteen months. Hartley found that 30 patients with idiopathic hypertrophy had been operated on with a death rate of 10 per cent. To these I add three cases with no deaths bringing the figures to 33 cases with a death-rate of 9 per cent. For malarial enlargement, to his 17 cases with about 13.5 per cent., I add 14 cases with 3 deaths giving a mortality-rate of 16 per cent. For wandering spleen, to his 23 cases with a mortality of 17 per cent., I add two successful cases reducing the death-rate to a flat 16 per cent. To his 4 cases of rotation of the axis of the spleen with one death may be added one successful case, making the mortality 20 per cent. He collected 11 cases of echinococcus and other cysts with 2 deaths. Since then one successful operation has been performed making the mortality to date 16.6 per cent.

No splenectomies have been recorded during the past two years for primary malignant disease of the spleen, a condition which offers very little to be gained from extirpation, as nearly every patient dies, either at the time of operation or subsequently from recurrence. For rupture of the spleen Hartley collected reports of 6 cases with 3 deaths. During the past eighteen months 16 patients have been operated on for this condition with but one death (McBurney's), and in that case rupture of the liver occurred at the same time. A death rate of 6 per cent. for an operation so severe as splenectomy and at such a critical time, speaks enthusiastically for its propriety. For hernia of the spleen 20 cases have been reported during the past two years all of which recovered by splenectomy, a wonderful record of good surgery. For tubercular spleen I find one case recorded that ended successfully as did one of my own. Fourteen cases are to be found in the literature of the past two years in which the diagnosis was not given, and of which 6 died, a mortality of 43 per cent. A careful analysis of these cases would be of interest to determine the causes of the high death-rate. As no blood examination was made in any of them they are of little value, though one must be inclined to believe that leucocythemia and bad adhesions must have been present in a number. Spanton collected statistics of this operation for the three decades immediately preceding 1895 and found that for conditions other than leucocythemia the death-rates for the first ten years was 80 per cent., for the second 45 per cent., and for the third but 20.68 per cent. He collected reports of 21 cases in which the operation had been done for wandering spleen, axis rotation, lymphosarcoma, cystic degeneration, injuries, and other conditions, with one death,—4.8 per cent.

Causes of Death.—The fatal results are nearly always due to shock or hemorrhage. Hemorrhage is extremely liable to occur in splenectomy because of the many vessels of extrordinary size to be divided and the very great difficulty encountered in placing the ligatures. The vessels are often equal in size to the femoral and the spleen is, especially when much enlarged, always in the way of the operator. The depth of the abdominal cavity adds to the difficulty. Shock is produced in these operations by traction on the pedicle, which in turn pulls on the diaphragm and also by the sudden removal of large amounts of blood from the circulation. This has been noticed particularly when the large spleen has been pulled through the abdominal wound. When the tumor is removed the large inelastic veins of the abdomen receive and retain a large proportion of the blood, thus robbing the circulation and causing death. Separation of the many firm adhesions so often found between the spleen and other structures has a powerful tendency to produce both hemorrhage and shock. The general condition of the patient of course very strongly influences the result of the operation. Leucocythemia, for instance, will render the operation almost uniformly fatal. Unrecognized severe pathologic conditions of other organs often determine the fatal result.

The two cases I have to report are as follows:

CASE I.—*Leucocythemia; Weight of Spleen Twelve Pounds and Seven Ounces; Death.*—Mrs. B., white, forty-seven years of age, married and the mother of one child, was admitted to the Columbia Hospital, April 27, 1897. She had suffered one year with an enlargement of the abdomen that had continually increased; her menses had been regular up to two months before admission; a urinalysis revealed considerable pus but this disappeared in about one week after admission. She had a well marked mitral regurgitant murmur which seemed to be well neutralized. A large mass on the left side extended from the pelvis to the sternum and seemed to be attached to the spleen. As the notch could not be felt and pus was present in the urine tubercular kidney was suspected. There were, however, three slight serrations along the right margin and the diagnosis was not made before operation. The uterus was considerably enlarged and well to the left, and the left appendage was low and matted. On May 10th, abdominal section was made and the tumor proved to be a spleen. This diagnosis was made, however, upon operation just before making the abdominal incision. It was slightly adherent and very large; it was carefully ligated off when its upper end was found to materially press against the diaphragm just below the heart. No blood was lost. As soon as this pressure was removed by pulling away the spleen the heart immediately stopped and a few seconds later respiration ceased and could not be aroused An autopsy made

a few hours later revealed a large pus tube on the right side and the left appendage bound down by adhesions; the liver was about twice its normal size; the heart was hypertrophied with shortened mitral valve. One flap was adherent allowing a distinct separation between the closed flaps; the pericardium contained several ounces of fluid and the coronary arteries were hard, and showed here and there calcareous deposits. Both lungs were large and congested, especially the left. The right kidney was normal and the left contained a small amount of pus. The spleen weighed twelve pounds and seven ounces. A previous blood examination by Dr. Carroll showed the condition to be one of fairly marked leucocythemia.

CASE II.—*Tubercular Peritonitis and Perisplenitis with Movable Spleen; Recovery.*—Mrs. W., white, fifty-five years of age, was seen with Dr. Chamberlin in January, 1898. For fifteen years she had had continual pain through the abdomen and chest and an abdominal tumor which she thought was a spleen. Her last confinement was at the age of thirty-six years and her last menstruation at forty. The abdominal pain had been markedly worse during the past two weeks. Upon examination the abdomen was found to be very tender, and a mass in the region of the kidney was found also to be very tender. In this case the notch was easily felt and the diagnosis of an enlarged and movable spleen was made. She was sent to Columbia Hospital, where on February 7th the tumor was removed. When the abdomen was opened a considerable amount of fluid escaped revealing tubercular peritonitis. There were no adhesions to any organ except the spleen, which was found to be the seat of the tumor and was considerably enlarged and studded on its surface with tubercles. It was removed without hemorrhage and the abdominal cavity irrigated with normal salt solution. The tubercular process was found to extend over the whole of the peritoneum and gauze drainage of the cavity was employed. With the exception of some of the usual symptoms of splenectomy she made a good recovery. Some months later, however, I learned she had developed pulmonary tuberculosis and I presume she has since died. Dr. Carroll reported as follows on the condition of the spleen: Weight, twenty-eight ounces; a microscopical examination of a portion of the spleen shows a chronic indurative splenitis with a chronic perisplenitis. The organ is engorged with blood and there is a general hyperplasia of its structure, involving both the elements of the follicles and the pulp. Many of the follicles show central areas of degeneration or necrosis, such as often appear in cases of bacterial infection, but no bacteria could be found in an examination of several sections stained with methylene blue and eosin. The tissues showed none of the pigmentation that goes with infection by the malarial parasite. Many of the vessels show a slight hyaline degeneration of their walls, probably an early senile change. The perisplenitis is well marked, the capsule is very much thickened and shows a few dense, fibrous nodular elevations upon its surface, and, in addition, an exudate that is undergoing organization.

THE PATHOLOGY AND TREATMENT OF WHITE SWELLING OF THE KNEE.[1]

BY A. B. JUDSON, M.D.,
OF NEW YORK.

PATHOLOGY, or knowledge concerning disease, may be said to be the prime requisite of the physician. It often stands higher in public estimation than the ability to cure. In the case of a patient whose symptoms are equivocal, for whom advice is sought in different directions, the physician who is in attendance when the nature of the disease finally declares itself has undisputed control. As knowledge goes before opinion, advice, prescription or operation, pathology should take the precedence in our medical studies. But how changeful is our Pathology! How fickle a divinity! It is said that the average life of a pathological doctrine is about 30 years. We learn, but with the prospect of having to unlearn; and the all-wise, unwise, public senses this and goes doubtfully away, "trembling, hoping, lingering, flying," to fanes where the divinities are not only fickle but meretricious.

In the consideration of the present subject, however, we are in a field where pathology and therapeutics have some of the stability of an exact science. It is a settled pathological doctrine that inflammation is prolonged by the exercise of the affected part. White swelling of the knee goes from bad to worse as long as the patient continues to subject the joint to the weight of the body when standing and the severe traumatism attending walking and running. It is surmised, and with good reason, that the foci in which are started the flames of articular osteitis, appear also at times in the bones of the upper extremity, but these being exempt from the forced drafts of traumatism which attend the machinery of locomotion, are in due time resolved and are thus but rarely recognized. The almost entire absence of shoulder disease, white swelling of the elbow and pulpy disease of the wrist is to be explained in this manner.

Based on this pathology is the positive prescription; give cessation of function to the inflamed bone and joint of the knee by arresting the double function of motion and weight-bearing. I am accustomed to do this in a certain way. To arrest motion a posterior upright is employed which extends sufficiently far above and below the knee to give an efficient leverage. It is padded at its ends to make comfortable counter pressure from behind forwards

[1] Read before the Orthopedic Section of the New York Academy of Medicine, October 20, 1899.

at the upper part of the thigh and the lower part of the leg, and it carries two cross-pieces, each half surrounding the limb, but not touching it, with four buckles at the ends of the cross-pieces in which are adjusted the two padded straps crossing the front of the limb to make pressure from before, backwards, above and below, and near the knee. This fixative brace is worn day and night.

To arrest the weight-bearing function the ischiatic crutch is used. This is worn only when the patient is up. It may be said to put the limb to bed while the patient runs about. It is applied with a high sole on the foot of the unaffected side. A point requiring especial attention in the adjustment of this crutch is the length of the seat strap. If, on the one hand, this padded strap is too long it allows the pelvic band to take too high a level whereby it makes uncomfortable pressure on the anterior superior iliac spine. If, on the other hand, the strap is too short it holds the pelvic band at too low a level, thus causing painful pressure on the pubes.

In a case in which the knee is unduly flexed the fixative brace may be used to correct the deformity, by taking advantage of the tractable quality of the steel, the knee and the brace having imparted to them, first one and then the other, an additional modicum of extension, or straightening. This is accomplished by buckling the pressure straps tighter and straightening the brace by the use of the vise and monkey-wrench.

Each case will be found to have its own peculiarities and contingencies and troublesome details which will have to be met individually. In general the success of mechanical treatment depends very much on the cooperation of the patient or, in the case of children, on that of the parent or other immediate attendant. It is often not out of place to say to the mother that the brace is to be worn not only on the child's limb but in her head.

The difficulty of securing proper attention at home to the details of treatment will generally be found to be the true explanation of failure to secure the best results. It is seen in some patients, who for this reason have failed to secure the best results, that the deficiencies occur chiefly in the line of efforts to secure final straightness of the limb. This is no trivial defect, because a knee ankylosed at a considerable angle is a source of lameness and disability. But as the prevention and the correction of flexion of the knee lie well within the power of so simple a mechanical device as a lever properly applied, a serious degree of flexion cannot become a feature of the result in a case in which medical attendance is rightly seconded by good management at home.

CASE I. *Incipient.*—A girl aged six years eight months was brought in on September 15, 1899, with a slight lameness in the right knee without pain. This had been noticed for about five weeks. In walking she accentuated the action of the left foot in order to throw the weight of the body on that limb rather than on the affected one. The left thigh four inches above the patella measured 11 inches, knee 9 inches, leg 8 3/8 inches; the right 10 3/8—9 3/8. The knee flexes 20°—170°. Manual attempts at further extension develop marked reflex. The patient illustrates the ease and convenience with which the ischiatic crutch, which was applied September 20, 1899, is worn. Extension of this knee could easily be made in a short time by the use of the fixative brace, which has not yet been applied. It will be of interest to note whether relieving the limb from the weight of the body will not of itself, without fixing the joint, lead in time to resolution with restoration of normal motion.

CASE II. *Complicated with Pott's Disease. Flexion Reduced.*—A boy four years of age had been lame in the left knee for one year. Flexion 20°—125.° A crutch was applied November 19, 1897, and fixative brace on February 7, 1898. Pott's disease appeared in the lumbar region and a spinal brace was applied December 12, 1898. Prognosis good. The knee is at 2°, practically straight. The three braces are easily and comfortably worn. The advantage of holding the pelvic band of the ischiatic crutch down to its proper level by a short seatstrap is emphasized in this case by the ample room which is thus left for the efficient application of a spinal brace.

CASE III. *Flexion Reduced. Absorption of Abscess.*—The patient, a five-year-old girl, came for treatment for the right knee, which had been lame for four years, January 18, 1897. Moderate subluxation. Flexion 55°—125°. Abscess attended by severe pain appeared at the outer and anterior side of the knee. The ischiatic crutch was applied March 5 and a fixative brace March 9, 1897. The apparatus is still worn. Prognosis good. The abscess has been nearly absorbed, and the knee is flexed 6°. Subluxation persists, but the femur is so far superimposed over the tibia that the stability of the limb will not be compromised.

CASE IV. *Flexion Reduced. Many Abscesses.*—A boy, aged one year and nine months was brought on August 26, 1895, with lameness of the left knee which had lasted a few weeks. Knee at 90°. A year later when he was again seen it was far advanced in destructive osteitis. Numerous sinuses on all sides of the knee; subluxation; general condition low. The fixative brace was applied with relief of the symptoms. Six months later the ischiatic crutch was applied. With this apparatus in place, the patient was at once active on his feet. The discharge is now moderate in quantity and some of the sinuses have cicatrized. The general health is good and prognosis favorable. The apparatus is still worn. The knee is at 10°; moderate subluxation. Frequent long absences, one of them for sixteen

months and two for seven months each, have marked the history of this case and have doubtless delayed recovery. In these intervals it is probable that the anxious mother consulted other authorities and the question of excision was probably duly considered. If the child's general condition was good at the time it might have been said, either that it was safe to continue to rely on mechanical treatment, or that excision would be well borne and should be done to hasten recovery. If, on the other hand, the general condition was bad, as it was at times in the extreme, it might have been said either that excision was necessary to save life or that the chances of recovery were not good enough to permit a resort to operative intervention. The present condition, however, gives good ground for confident expectation that the final result will be combined straightness, length and stability of limb in greater degree than may be looked for after excision.

CASE V. *Abscesses. Recurrence of Flexion after Recovery.*—A girl three years and four months of age had been lame for six months in the left knee. Marked flexion. Left knee $8\frac{7}{8}$; right knee $7\frac{7}{8}$ inches. On January 24, 1889, the fixative brace was applied and three months later the flexion was entirely reduced. The ischiatic crutch was applied March 18, 1889. In August, 1889, and June, 1890, sinuses appeared which were finally cicatrized in August 1890. In July, 1892, a third abscess opened and two months later had finally closed. In October, 1894, motion was between hyperextension 5° and flexion 30° and treatment was suspended. In October, 1898, there had been no symptoms, but the knee was flexed with motion between 28° and 48°. The fixative brace was re-applied, against the patient's will, and flexion has been reduced to 10°, with good prospect of complete reduction. No subluxation. She now prefers to retain the brace and would not mind wearing it always, feeling that it adds greatly to her ability to walk and run. This will probably not be necessary. When the bones are mature their articulating surfaces will adapt themselves to each other so that the femur will rest securely on the tibia in the straight position.

CASE VI. *Deformity after Incision. Not Reduced.*—A girl ten years of age had suffered with the left knee for three years. Two operations for tuberculosis of the knee had been performed in general hospitals. The articulating surfaces had been sawn off and the knee was practically motionless at 35° of flexion. The fixative brace was applied for the correction of the deformity in March, 1896. It is still worn. The knee was at one time at 20°. It is now at 30°. The brace has been worn constantly, and the patient's attendance at the dispensary has been regular, but the prospects are that the flexion will be a permanent disability. It has been impossible to inspire the patient or her parents with confidence in the efficacy of mechanical means. The case illustrates what has been said about the way in which medical attention may be thwarted by a failure to secure cooperation in the patient's home.

CASE VII. *Deformity after Operation. Reduction.*—A three-year-old girl, lame in the left knee, was brought August 2, 1895. Flexion at 22°. The fixative brace was applied August 9, 1895. The flexion has been completely reduced, but has been permitted to return. It is now 12°. The patient is likely, however, to have a straight limb, as the ankylosis is not very firm and the child, with good parental care, is approaching an age when she will, as happened in Case V., take a personal interest in her own case.

CASE VIII.—Boy, aged seven years and six months, lame for eighteen months in the right knee; the fixative brace was applied January 24, and the ischiatic crutch January 27, 1893. The patient was presented to the Orthopedic Section on April 20, 1894. The crutch was discontinued in September, 1896, and the fixative brace in January, 1897. The knee now flexes 8°—75° and imparts no defect to his ordinary walking gait.

CASE IX. *Reduction of Flexion of Ten-Years' Standing.*—A boy fourteen years of age, had been lame from infancy in the left knee. Beyond the swelling and limitation of motion there had been but little trouble for ten years. Flexion 25°—55°. The fixative brace was applied to straighten the knee March 23, 1891. In March, 1893, the knee was straight and in July, 1894, it was hyperextended 10°. The brace was removed in January, 1896. At present flexion is 0°—20°, a result largely due to his intelligent interest in the progress of his own case.

CASE X. *Recurrence of Flexion. Abscesses.*—A boy of eight years had for four years suffered with his right knee. Marked subluxation. Flexion 30°—80°. Sinuses. In March, 1885, the Thomas splint for protecting the limb from the weight of the body, and a fixative brace were applied. The patient was presented to the Orthopedic Section on March 19, 1886. On January 8, 1887, the ischiatic crutch was applied in place of the Thomas splint. The knee was straightened and at one time was hyperextended 2°. The sinuses closed. At present the flexion is at 25° with marked subluxation and very little motion, a result due partly to the late stage at which treatment was begun and in large measure to a failure, too often encountered, to obtain thorough cooperation.

CASE XI. *Mild Case. Abscesses. Result 20 Years after Treatment.*—A boy six years of age had had for five months, swelling, pain, and limited motion of the left knee; on May 7th a Thomas splint and on May 13, 1878, a fixative brace were applied. In the following summer a sinus appeared and the abscess discharged for four months Several pieces of cancellous bone were extruded, one of them being evidently a fragment from the surface underlying the articular surface of a femoral condyle. The fixative brace was removed in February and the Thomas splint in April, 1879. There was ¾ of an inch lengthening and recovery with normal motion and locomotor ability. As the patient was traveling he could not be present at the meeting. Inspection, however, would have revealed nothing objective,

except a depressed scar, 1½ x 1, attached to the inner condyle. He says that when being measured for clothes the limb is a ¼ of an inch longer than the unaffected one. There were exceptional reasons for expecting a good result in this case. Among them was the probability that tne affection was of a comparatively mild character. It was not the typical insidious osteitic invasion, after which we may, as a rule, be glad to secure a strong, straight and useful limb, albeit motion may be limited or absent from the joint.

CLINICAL MEMORANDUM.

A BRIEF REPORT OF AN EPIDEMIC OF TYPHOID FEVER IN WORTHVILLE, N. C., DURING 1898.

BY CHARLES C. HUBBARD, MD.,
OF WORTHVILLE, N. C.

THIS is a factory village of three hundred and fifty inhabitants, situated on Deep River. The town has been built about seventeen years. There are forty houses belonging to the factory company, and about thirty others within a radius of half a mile from the center of the village. The forty houses are supplied with water from nine wells. One of these has never, or at least not lately, been much used by the families for drinking purposes. Durthe past year four of these went dry, and the forty families used water from the other five, one of which I shall speak of more fully later.

Osler, in the last edition of his text-book says that "outbreaks of typhoid fever are more likely to occur in extremely hot and dry seasons when the water-supply is very low," giving as a reason the more complete drainage of the soil, which carries the germ into the water-supply, and from thence into the alimentary canal of those who drink it.

We believe this for we had had just such a season. If there are 10,000 germs of typhoid in a well which contains two feet of water, it is reasonable to suppose that the man who takes a drink of this water is more liable to contract the disease than he who drinks from a well containing ten feet of water and the same number of germs.

The water-supply of this immediate section had been extremely low during the previous eighteen months, necessitating the sinking of wells deeper in sixteen instances within a radius of less than a mile, although there have been only five cases of typhoid fever outside of the families supplied with water from the nine wells mentioned. These cases were:

(1) That of a boy aged three years living near the village; (2) that of a girl twelve years old, living near the edge, and above the town proper. This was a case of "walking typhoid" and she was in bed only part of the time; (3) that of my own little girl four and a half years old, who, when attending Sunday-school drank water repeatedly from the well which was afterward found to be contaminated. My own well had to be sunk deeper, so this is not conclusive, though there has never before been a case of typhoid fever among those using water from this well; (4) that of myself, which occurred late in the season, the fever having been contracted after treating 46 cases; and during the treatment of these cases I was often obliged to eat and drink at the homes of my patients; (5) that of the fourteen-year-old daughter of the superintendent of the factory, whose well is in a direct line 135 feet below the privies of two families in one of which the first case of typhoid fever occurred. No other member of his family had typhoid.

The five wells which did not go dry were the principal water-supply of the forty families before mentioned. For several weeks the water in two of these was so low that when a bucketful was drawn up it had to be set down for a few minutes to allow the mud to settle before the water was poured off. There was such a scarcity of water that the town commissioners passed an ordinance prohibiting the use of the water for any purpose except cooking and drinking. The well from which the first six cases started is located in a block 250 feet long by 190 broad, containing six dwellings, five privies, four wood piles, one wood house, one chicken-lot and coop, and stamping-ground for one cow and one horse in daytime. In the same block there is a well not used for drinking purposes. Within 115 feet of the infected well are five privies, the nearest of which is 80 feet. Into the one 100 feet away were thrown, the year before, the undisinfected discharges of a typhoid patient. Just across the street 50 feet from this well, there was a case of typhoid the year before, the discharges from which were thrown into a ditch less than 10 feet from the well. I was not living here at the time, but have this information on good authority. Just across the street from this same well, at distances of 100 and 160 feet respectively, are four more privies, the drainage of which leads directly from the well. During the spring and summer the water from this well contained much mud and trash, and had a bad taste and odor, yet the families continued to use it for drinking and cooking. When the well was dug deeper, about one foot of mud, with rocks, sticks, and trash, was removed, also timbers which had been placed behind the wall fourteen years ago to prevent caving. Planks an inch and a half thick were thoroughly rotten and timber four by four inches could be torn into shreds. After the wall was replaced the water was drawn off twice, after which it appeared to the naked eye, to be pure, but on examination by the bacteriologist of the State Board of Health showed over 4000 bacteria to the c.c., some of which were intestinal bacilli. Since this examination the water has not been used for any purpose. Four months later a professor of bacteriology in one of our State colleges examined samples of this water with similar results.

Thirty-two cases of typhoid have occurred in the families using water from this well, three of which proved fatal. A young married woman, aged nineteen, living in the country, visited her sick mother living in the town three or four times, staying all night once or twice; soon after her visit she had a severe attack of the disease. Her people used water from this well. Her child, two and a half months old, continued to nurse from her for about a week after she was taken sick, and three weeks

later it was taken with fever; dry tongue, enlarged spleen, tympanites, and characteristic stools.

Another married woman, aged twenty-three, also living in the country, but on the opposite side of the town from the above case, stayed for several days at her fathers, whose house is within fifty feet of this well, and from which he derived his water-supply. She had a long, tedious attack of typhoid fever.

These two additional cases, which seem to have started from this well, make thirty-four cases which originated from this source. This does not include seven or eight cases which resembled typhoid closely but which were not well-defined examples of the disease.

The total census of the families in which the thirty-two cases in town occurred is sixty-nine, thus, nearly one-half were affected. This number, sixty-nine, includes all the members of all the families who used water from this well. In the whole town there were sixty-three pure cases with a death-rate of about 10 per cent., besides several suspicious ones. Thus we see only thirty-one cases have occurred whose origin is unknown. Five of the thirty-one drank water frequently from the infected well and it is reasonable to infer that at least forty cases originated from this single source of contagion. Eighteen of the sixty-three were under twelve years of age.

MEDICAL PROGRESS.

Pancreatic Hemorrhage and Pancreatic Cysts.—ANDERS (*Jour. Amer. Med. Assoc.*, December 2, 1899) has made an exhaustive study of pancreatic hemorrhage and has presented the reports of forty cases in tabular form. Twenty-five of these occurred in the male and nine in the female sex, while in some instances the sex of the patient is not mentioned. Nearly one-half of the patients were between forty and fifty years of age. While pancreatic hemorrhage as an immediate cause of death must be admitted to be rare, it is still of greater clinical and medico-legal importance than most persons suppose. Death in most of the instances mentioned occurred in a few hours. Life was rarely prolonged as much as three days. The direct cause of death is not always obvious. For instance, patients have died in a few hours when the loss of blood did not amount to more than eight ounces. Such deaths are due apparently to shock.

MCARTHUR (*ibid.*) contributes an article on pancreatic cysts, having been able to collect and tabulate the reports of 104 cases in which patients submitted to operation. Such cysts are best classified according to their walls and are either retention cysts, cystosarcomata, or adenocystomata. The retention cysts are the most important clinically. They are similar in origin to the ranulæ which occur in the mouth. The duct or some branch of it may become obstructed as a result of traumatism or by stone, or, possibly, by a blood-clot. The easiest operative treatment is known as the "two-step" drainage plan. By this means convalescence is prolonged and there is a possibility of a fistula being left, but the danger from shock and hemorrhage is less than when the cyst is extirpated. If a pancreatic cyst is suspected to be other than a simple retention cyst, extirpation should be performed if possible in order to prevent malignant recurrence.

Aortic Valve Disease.—THEODORE FISHER (*Edinburgh Medical Journal*, November, 1899), in a short and practical article on the morbid anatomy of the aortic valves, brings out a few points of general interest. He distinguishes two main forms of chronic disease of this valve in adults. In one the disease is associated with disease of the aorta, and in the other the aorta is almost invariably healthy. In one the aortic segments are thickened and deformed on account of an increase in the fibrous connective tissue, but calcareous changes are absent; in the other there is little or no fibrous tissue, but great deformity due to calcareous deposit. In one, again, the disease seems to be an extension from the aorta; in the other it appears to arise primarily in the segments of the aortic valve. One disease usually produces aortic regurgitation, unassociated with any stenosis; but the other almost invariably produces stenosis, which is not infrequently uncomplicated by regurgitation. The etiology of these types of disease is obscure. Aortitis is probably the initial disease in the first type. Whether this aortitis is of syphilitic origin or not, there seems to be but one opinion, and that is positive, but syphilis alone is not the only responsible factor.

The etiology of the calcareous form is still undecided. Although text-books ascribe to syphilis, gout, alcoholism, and Bright's important etiologic relations to this disease, Fisher believes that such conclusions rest on very unsatisfactory data. He attaches considerable importance to mechanical strain.

Bacteriology of Typhus Fever.—ANDREW BALFOUR and CHARLES PORTER (*Edinburgh Med. Jour.*, December, 1899) fill out a preliminary series of investigation contributed to this same journal in February, 1899. The studies were made upon forty-three cases of typhus fever, both in the acute and convalescent stages, from the wards of the Edinburgh City Hospital, the Convalescent Home at Musselbourgh, the Leith Public Health Hospital, and the Dundee Hospital for Infectious Diseases. In addition, the blood from 20 quarantine cases of typhus, 46 cases of typhoid fever, 21 cases of scarlet fever, and 2 of measles was examined. A large number of bacteriologic and microscopic blood examinations was made from persons suffering from other ailments and from normal healthy individuals. In all, some 220 blood examinations were made. A large number of post-mortem investigations was also made. Especial attention was given to the bacteria known to be normally present in the deeper layers of the skin, since the method of collecting the blood by simple puncture of the skin was practised.

In thirty-six of the forty-three cases of positive typhus (eighty-eight per cent.) a diplococcus was found. It was non-capsulated, non-motile, and did not possess flagella, though it showed a marked oscillatory movement, and could be seen to turn over frequently. It stained well with the ordinary stains, and retained Gram's stain. Facultative anerobe. It produced a cloudiness in broth, a white cement-like streak in agar and on blood-serum; its

growth on potato is not distinctive. Gelatin is liquified. It does not produce gas in glucose broth. Milk is coagulated in forty-eight hours, and an acid reaction in lithmus broth is evident in one day. The most favorable temperature for growth is 37° C.

In eight of nine post-mortem examinations on typhus fever patients this organism was obtained in pure culture, but in none of their examinations of the bodies of those dying from other disease was this organism found.

The diplococcus here described resembles in most of its details that found by Dubief and Bruhl, who in 1893 made a thorough study of typhus in an outbreak of the disease in the Parisian prisons. These observers, however, never succeeded in cultivating the organism from fresh blood.

Animal experiment was not altogether satisfactory, though the organism derived at autopsy was markedly pathogenic, producing in animals symptoms and post-mortem appearances closely resembling those of a continued fever.

Municipal Control of Prostitution.—DYER (*New Orleans Med. and Surg. Jour.*, December, 1899) has taken the trouble to look up the municipal control of prostitution in a number of large American cities, and finds that:

1. There is at present almost universal absence of active regulations governing prostitution in most of the cities and States of the United States; the houses of prostitution and their inmates are recorded by the police in some cities, but even then the records are incomplete; no information is kept by the authorities upon the question of venereal diseases among the prostitute class.

2. The absence of statistics and the lack of provisions for determining and recording and treating venereal diseases in this class in large degree create the general indifference to existing conditions.

3. While the health authorities are busied with the study of other contagious diseases, such as diphtheria, scarlet fever, variola, and the like, the venereal diseases are not even considered, although their occurrence is really greater in proportion to population than most of the diseases studied by them.

In order to accomplish reform he believes that it is essential to recognize prostitution and license it so long as laws are made differently for men and women. If no restriction is put upon the male sexualist who seeks women, no *criminal* restriction should be put upon the woman whom he seeks. If the prostitutes are licensed a police record can be kept of their residences, state of health, etc., and a regular police inspection of their homes and public resorts can be made. Dyer is opposed to a police examination of the women themselves, believing that better results could be obtained from a voluntary examination in a more private manner by regularly appointed physicians. Physicians should also be encouraged to report on blanks furnished by the city cases of venereal disease occurring in their practice.

A Modified Vaginal Fixation for Cystocele and Prolapse of the Uterus.—WATKINS (*Amer. Gyn. and Obstet. Jour.*, November, 1899) describes a modified vaginal fixation which he has employed in cases of uterine prolapse and cystocele after the menopause. It differs from the usual vaginal fixation in that enough of the anterior vaginal wall is excised to obliterate the cystocele, after the sutures are inserted and tied; in suturing the anterior vaginal wall to the broad ligament, and in incising the posterior vaginal wall and suturing the cervix so as to hold it in about its normal position. The sutures employed are silkworm gut. They should be removed at the end of four weeks. The operation is not advised by the author in cases in which the patient is still in the child-bearing period, but in difficult cases of uterine prolapse, occurring after the menopause as a result in part of senile atrophy, the operation is one which if well performed will yield a perfect result.

The Contagiousness of Inherited Syphilis.—KOLIPINSKI (*Maryland Med. Jour.*, November 25, 1899) narrates the histories of two cases which strikingly illustrate the contagiousness of inherited syphilis, a matter which has recently been questioned by Simes in an article which appeared in the *Philadelphia Medical Journal*, October 21, 1899. A maternal grandmother, over sixty years of age, cared for her grandchild who suffered from coryza and sore mouth of a syphilitic character. She had a habit of wiping the child's mouth out with her finger although warned that this was a dangerous procedure. Soon the initial lesion of the disease appeared on the dorsal surface of her index finger near the tip, and later she presented the ordinary symptoms of the secondary stage. The second history quoted tells how a paternal grandmother who took care of a syphilitic infant developed a primary sore on the palmar surface of the right ring-finger. Her son, a boy of seventeen years, had a habit of opening the clogged rubber nipple of the nursing-bottle by sucking it. When first seen he presented the lesions of the secondary stage of syphilis. No primary scar could be found upon him either in the mouth or upon the genitals, but the initial lesion was doubtless extra-genital.

Sulphate of Magnesium in the Treatment of Dysentery.—ROUGET (*Brit. Med. Jour.*, November 18, 1899) has employed the sulphate of magnesium in the treatment of tropical dysentery as recommended by Wyatt-Smith. The drug was administered in doses of 1½ drams to 2 drams, combined with 10 minims of aromatic sulphuric acid in syrup and cinnamon water. The dysenteric stools entirely disappeared in from eighteen to thirty-six hours. Soft, yellowish feces were passed for a time and in a few days the cure was complete. During convalescence, a powder containing salicylate of bismuth, grs. 15; benzol-naphthol, grs. 10, with the addition sometimes of Dover's powder, grs. 3, was given three times a day. The patients were kept on an absolute milk diet. If the treatment by sulphate of magnesium was discontinued too soon, or if the patient returned to an improper diet, such as rice and curry (the tests were made in India) a relapse followed. The advantages of this method of treatment are strikingly set forth in a table which shows that under the treatment formerly employed by Rouget, forty-one pa-

tients suffering from dysentery were given ipecacuanha, bismuth salicylate, salol, or opium. Of these three died, thirty-one recovered, and eight were unimproved. Of fifty-six treated by magnesium sulphate, none died, fifty-four recovered, and two were discharged improved. Magnesium sulphate does not seem to be of much value in chronic dysentery. The two cases marked "improved" in the table were of a chronic character.

Relapsed Clubfoot.—TAYLOR (*Maryland Med. Jour.*, December 2, 1899) says that in all cases of true congenital talipes equino-varus, if the foot is not mechanically fixed in an over-corrected position after operation so that it can be walked on, it will relapse into just as bad if not a worse position than before operation. He mentions three such cases. The patients had had tenotomy done in infancy and wore plaster-of-Paris casts for a month or more, and within six months or a year they were worse than before, so that a simple tenotomy no longer sufficed to correct the deformity. The best surgical relief of talipes equino-varus will be worse than useless if correction is not maintained by a suitable ambulatory brace for months afterward. Such a brace must exercise pressure at three points: (1) at the metatarsal phalangeal articulation of the great toe; (2) at the inner side of the heel, and (3) at the calcaneocuboid articulation on the outer side of the foot. There must be a stop-joint at the ankle to prevent a recurrence of the equinus. The inner side of the brace and shoe must be lower than the outer side to prevent supination of the foot. The author strongly condemns any mutilating operation to the bony frame of the foot, such as removal of the astragalus, these operations being contrary to the best interests of the patient.

Disinfection in Contagious Disease.—WALSH (*The Therapist*, November 15, 1899) after enumerating the difficulties in the way of carrying out perfect fumigation of a room by either sulphurous acid, chlorin, or formic aldehyd vapor, and the impossibility of obtaining absolute disinfection by spraying and washing with disinfectant solutions, and by dusting powders, says that fresh air is perhaps the most important of all natural disinfectants. During the illness, free ventilation is invaluable, while after fumigation the room should be flushed with air for twelve or twenty four hours. During the illness all excreta should be systematically disinfected. This applies not only to the stools but to the sputa of tubercular, pneumonic, and diphtheritic patients, and to all dressings and remnants of food. The last should at once be thrown into the fire. In order to carry out these and other necessary precautions in connection with the clothing and other articles which come in contact with the patient, skilled attention and at least one vacant room in addition to that occupied by the patient are absolutely necessary. It will be seen at once, therefore, that proper disinfection during contagious illness is impossible in the houses of poor, especially in large cities where most cases of contagious disease arise. The author insists therefore on the necessity of suitable infectious hospitals in every sanitary district. When rational and thorough precautionary measures are taken in the homes and hospitals he looks to see a marked decrease in all diseases of a zymotic type.

THERAPEUTIC NOTES.

For Branchopneumonia in Children.—COUTTS of London considers belladonna in large doses to be most helpful in this disease, the dyspnea being relieved, the heart and respiration stimulated, the temperature lowered, and the bronchial secretion favorably affected. He confines his medication to the drug in question, even in severe cases, and does not regard the symptoms which it may produce (redness of the skin, occasionally amounting to a scarlatinal rash, dilatation of the pupils, irritability, slight excitement or delirium) as serious in the majority of cases. He gives ¼ of a grain of the extract every three or four hours, alike to nursing infants and children of six or seven years of age. The dyspnea should be relieved after a few doses, and improvement in the other symptoms then expected.

For Blepharitis Marginalis.—

℞ Antimonii sulph . . . . . 3 ss
Lanolini . . . . . 3 ii
Vaselini flav. . . . . 3 i.

M. Ft. unguentum. Sig. Rub a little on the border of the lid at night. Wash off with warm water and a bit of gauze in the morning.

CARRA has used this ointment with great success in his ophthalmic clinic at Rome, and looks upon it as superior to mercurial or ichthyol preparations. No irritation or even burning sensation follows its application, crust-formation soon ceases, and the eyelashes grow in again very quickly.

Medicinal Treatment of Bubonic Plague.—The following drugs are recommended by H. LORANS, after an extended study of cases treated by various methods. Carbolic acid and bichlorid of mercury both do good service. The former is given in 4 or 5-drop doses in a potion every three or four hours. There is no specific toleration of carbolic acid in plague cases, and the usual indication for ceasing its administration, dark urine, is observed. Patients do, however, show toleration for large doses of sublimate, taking as much as 1½ grains in twenty-four hours without signs of salivation or stomatitis. They improve rapidly under the action of the drug. At the onset 10 grains of calomel, followed by some demulcent preparation, frequently cause the nausea and headache to disappear. Antipyretics are not to be recommended, as they enfeeble the heart and increase the danger of collapse, while having no effect on the temperature. Strophanthus is useful as a heart stimulant. The buboes are best left alone until fluctuation is evident, when incision, etc., is practised as in case of any other abscess. Early incisions or injections are dangerous because of probable infection of the periglandular tissue. Applications of belladonna in glycerin may be used to relieve pain in the glands.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

THE MEDICAL NEWS FOR 1900.

THESE are stirring times in the realm of medical science as well as in the commercial world. Important discoveries are multiplying and each one is rich in suggestion for new lines of investigation. The restless spirit of science is revealing daily more and more of the mystery of disease and the secrets of its cure. The supply of medical literature is constantly on the increase, pressing for immediate publication.

To more fully meet the demands of the times the MEDICAL NEWS will, with the beginning of the new year, be permanently enlarged to forty pages of text and the typographical arrangement of the page will be so modified as to accommodate an increased amount of material without sacrificing legibility.

In its new form, the MEDICAL NEWS will be enabled to publish not only original communications with increased promptness but it will afford space for more complete and more numerous excerpts from our domestic and foreign exchanges. A large and effective staff has been organized to do the work in this department, and our readers may expect the most recent and advanced medical thought from every part of the world, presented with promptness and completeness. Everything of practical or scientific interest will be gathered, boiled down and made ready for prompt assimilation. The department of Echoes and News will also present the latest and most important items of interest.

In order that the profession may become more intimately acquainted with the leaders of medical thought in France and Germany through articles direct from their pens, the MEDICAL NEWS has arranged to publish during the months intervening between the present and the assembling of the International Congress in Paris a number of original articles by prominent men in those countries. Some of these articles are already received and are being translated for publication.

The spirited controversy that has been carried on in our columns during the past year by Sanarelli and his American critics in reference to the bacillus icteroides, while it has helped to crystallize the features of the investigation which have been definitely settled still leaves the supreme question at issue. The interest attached to the subject of yellow fever will call for reports in our columns of further investigations and discoveries as they are made. The report of Agramonte's recently extended investigations in Cuba upon this subject is now in our hands and will be presented at an early day.

The report of the use of the modified yellow-fever antitoxin serum as prepared at the New York Quarantine under Dr. Doty's supervision, is also ready for publication in our columns at an early date. These observations were made at Tampico, Mexico, during the recent invasion of yellow fever there.

These interesting lines of study and the changes which have been outlined cannot fail to commend themselves to our readers, and together we enter upon the new year with pleasurable anticipation.

THE PSYCHOLOGY OF CONVERSION.

IT is a curious thing that men know more of the idiosyncrasies of a vagrant comet that may hit or miss us in its path than they do of the mental personality of their friends and families. The matter of learning men is one of the bases of a successful life, but such knowledge is called "intuitive" or "natural aptitude," or any thing but what it really is, a scientific perception of classified temperaments

and their natural working out in active life. Religious convictions, and especially that religious experience known as conversion, which is a natural accompaniment of adolescence in certain minds with given training, are so essentially an element in social relations that they offer a clue to the mental makeup of the individual. But this fact that might mean so much to the teacher, the physician, and the parent in the development of the mind of a boy or girl is apt to be ignored save from a rather narrow moral standpoint.

Professor George Albert Coe has worked out this idea, and has published results in "A Study in the Dynamics of Personal Religion," which appears in the *Psychological Review*, vol. vi, No. 5, p. 484. He abandons the saints and skips the classic conversions, and comes down to the you-and-me-point of view. A series of careful questions and tests put to some seventy or eighty persons of education and discrimination has revealed that conversion is an experience of temperament and of environment rather than a universal human experience. A critical study shows that striking conversions occur chiefly in those denominations that definitely aim to secure them. There was in all cases a striking corelation between each person's experience and his degree of suggestibility. Those that expected joy, ecstasy, and a sense of forgiveness experienced them, even to the point of hallucinations, in just the proportion they were able to feel such emotions when they were expected in other relations of life; while others equally expectant, but who were in daily life more critical and less suggestible, were disappointed.

The whole gamut of emotional experience in religion, he holds, might easily be prophesied if the factors of temperament and environment were correctly judged.

"Would you cast the horoscope of a human life?" says Fouilleé. "It is not to be read in the constellations of the sky, but in the actions and reactions of the interior astronomical system—do not study the conjunction of the stars, but those of the organs." Similarly Dr. Coe adds: "Would you understand the emotional aspects of religious experience? Do not ascribe them to the inscrutable ways of God, but to ascertainable differences in men's mental constitutions; do not theorize about divine grace, but study he hidden workings of the human mind."

MARRIAGE AND CERTAIN PHYSICAL DEFECTS.

It is sometimes a puzzling question that is presented to the physician when a patient or his friends consult him regarding the advisability of marriage with a person suffering from certain physical defects, and especially regarding the probability of the defects appearing in the next generation. The medical world is not definitely persuaded of the transmission of acquired characteristics. Even the question of heredity in family traits is not always clear.

A very interesting commentary on the questions thus brought up and one that throws light on the practical aspects of the subject is the book called "Marriages among the Deaf in America," by Edward Allen Fay, whose large experience among the deaf and his familiarity with all the aspects of questions relating to them makes him a reliable authority. Statistics show that about seven per cent. of the children born of parents one or both of whom were deaf, are congenitally deaf or become so at a comparatively early age. This is much more frequent than the occurrence of deafness among the general population of the country, so that evidently the physical defect in the parents stands as a determining influence in many cases. An analysis of the statistics shows how that influence is exerted. The marriage of congenitally deaf people who are blood relatives of near degree is especially fruitful in deaf children. The marriage of individuals who have relatives that are deaf, especially when the deafness is congenital or acquired in early life, is much more liable to be followed by the birth of deaf children than if the parents represent isolated cases of deafness in their respective families. Acquirement of deafness when very young seems to be a hereditary trait in some families, and to be due to an irresistive condition of the tissues that make up the auditory apparatus.

The marriage of individuals who are deaf themselves, whether the defect is congenital or acquired, but who have no relatives who are deaf, is not liable to be followed by the birth of deaf children. It is to be noted, however, that the heredity of the defect need not be direct. For instance, the occurrence of deafness in a brother or sister or in an uncle or aunt may signalize the existence of a family

strain or tendency to defective auditory development. The family tendency may skip a generation, too, and the occurrence of deafness may be an atavistic return to the grandparents' condition in the matter of audition. In a word, the carefully compiled and collated statistics confirm certain principles in the matter of conjugation that have been gaining ground of late years. It is not simple consanguinity in marriage that constitutes the danger to the offspring so much as consanguinity with like pathological tendencies. Isolated examples of defect even when congenital are not liable to be perpetuated, while the absence of defect in an individual whose family tendencies are in the line of defect may, nevertheless, result by atavism in defective offspring. It is family traits rather than individual peculiarities that constitute influences in heredity.

ECHOES AND NEWS.

NEW YORK

A Rich Charity Patient.—A charity patient with $212 in his clothing was removed to Bellevue from Roosevelt Hospital on December 20th.

A $40,000 Dormitory on Randall's Island.—Horgan & Slattery, the city architects, have filed plans with the Building Department for a three-story brick, galvanized iron and limestone structure to be erected for the City on Randall's Island at a cost of $40,000. The building will be devoted to sleeping quarters and play-room for children.

Officers of the New York Academy of Medicine.—At the annual meeting held December 21st the following officers were elected for the ensuing year: Vice-president, G. L. Peabody; trustee, A. Jacobi; treasurer for trustees, R. H. Sayre; treasurer, H. L. Collyer; members of the committee on admission, C. E. Nammack, J. B. White (to fill vacancy); member committee on library, Alfred Meyer.

Must Give Records of Patients.—Commissioner of Charities John W. Keller issued an order on December 22d to all charitable institutions in the city, especially to Bellevue Hospital, by which doctors are required to give all desired information regarding patients to clergymen. The order was issued after a conference in the Commissioner's office between the doctors of the Bellevue staff and several priests of the Carmelite Church, which has a chapel in Bellevue.

The Ramapo Water Scheme.—The general subject of water-supply, and especially the Ramapo water scheme, was the subject of discussion at a recent meeting of the City Club of New York. The strongest arraignment of the Ramapo contract was made by Dr. Herman Biggs; he presented a convincing argument showing the necessity of the City owning the water-sheds in which the supply of water is collected. In no other way can the pollution of the source be prevented and disease be kept out of the drinking-water. A private company will concern itself only with its profits.

A Bill for a New York Sanatorium for Consumptives.—Dr. George W. Brush of Brooklyn is chairman of the committee appointed by the State Legislature to investigate the subject of establishing a State hospital in the Adirondacks for the treatment of pulmonary tuberculosis. Dr. Brush will present his report early in the session, and accompany it with a bill providing for an appropriation of $200,000 for the building of the sanatorium. The Governor is to appoint five citizens who shall constitute a board of trustees, to serve for three years. Accommodation is to be furnished in the sanatorium for at least two hundred patients.

Obituary.—Immediately after the stated meeting of the Orthopedic Section of the New York Academy of Medicine, held on December 15, 1899, had been called to order' it was on motion adjourned out of respect to the memory of Dr. Samuel Ketch, and a committee was appointed by the Chair to express the sentiments of the Section.

The committee reported as follows:

The Orthopedic Section of the New York Academy of Medicine desires to express its profound grief at the sudden death of Dr. Samuel Ketch, one of its most useful and honored members.

An original member of the Orthopedic Society, since merged in the Orthopedic Section of the Academy, he served as its secretary in 1889 and as its chairman in 1891, presented several valuable original contributions, and was at all times prominent in everything pertaining to its best interests and progress.

Identified with the practice of orthopedic surgery for nearly twenty-five years, and in every way devoted to the advancement of his chosen work, his life was one of consistent uprightness and honest and successful effort.

[Signed.] HENRY LING TAYLOR, NEWTON M. SHAFFER, REGINALD H. SAYRE. } Committee.

PHILADELPHIA

Health Reports.—The total number of deaths in this city for the week ending December 23d was 419, or a decrease of 34 from those of last week, and of 231 from those of the corresponding week of 1898. Returns of contagious diseases were as follows: diphtheria, 119 new cases, 22 deaths; scarlet fever, 24 new cases, 5 deaths; and enteric fever, 46 new cases, 2 deaths.

Conflict over Evan's Museum.—Differences have arisen between the city of Philadelphia and the executors of the late Dr. Thomas W. Evans, who recently bequeathed to the city an estate valued at over $3,500,000 to establish a free museum and dental institute. A series of protests have been filed by Dr. Evans' heirs to this disposition of his estate, and although rumors of an amicable settlement

between all concerned are being bruited about, those qualified to know state that a lively legal fight must ensue before the matter is definitely settled by the courts.

A Statue of Dr. Pepper.—A statue of the late Dr. William Pepper was formally presented to the University of Pennsylvania on December 20th. It is done in granite, after a design by Leigh Hunt, and was presented to the trustees on behalf of the Pepper Testimonial Committee by Ex-United States Senator Edmunds. The announcement was made that Mrs. Frances Sergeant Pepper, the widow of Dr. Pepper, had given the sum of $50,000 to the University as a fund to carry on the work of the Museum begun by her husband. Provost Charles C. Harrison accepted the statue on behalf of the trustees.

A Black List of Non-paying Patients. — The physicians of West Chester, a near suburb of Philadelphia, are reported to have formed a mutual agreement by which it is proposed to keep a general "black-list" of people who will not pay their doctor's bills. It would seem that West Chester suffers to a great degree from that very common pandemic, the leading symptom of which is disinclination on the part of the individual to remunerate his medical attendant, and that the doctors of this town hereafter agree to refuse medical services to all persons who by their past actions are classed among those able but unwilling to pay just accounts for physicians' attendance.

Philadelphia's Insanitary Schoolhouses. — Dr. Taylor, Medical Inspector, reports that many of the school buildings are positively uncleanly, insufficient ventilation commonly prevails, provisions for lighting and heating are in many instances unsatisfactory and crude, and urinals and closets for the use of the pupils are often found to be wholly inadequate, uncleanly, and sometimes highly repulsive. There are certain paragraphs of the report which encourage the reader in believing that sanitary reform is progressing in the public schools, but as a whole the document is discouraging and demonstrates a sad lack of many requisites upon which the health of the school children largely depend.

Lecture on Eddyism. — The growth which Christian Scientism has obtained in this city was well illustrated one evening this week, by the audience of several thousand persons which crowded fashionable Horticultural Hall, and listened, evidently with rapt attention, for two hours to the remarks of a Judge William G. Ewing of Chicago on "Christian Science: the Religion of Jesus Christ." The creed was defined as a "belief that the true disciples of Jesus Christ, those who have entire faith in His teachings, have the power to do the works that He did, *viz.*, heal the sick, give sight to the blind, make the lame walk; and that they should in accordance with His word, do even greater works than these, and this without the aid of drugs, diet, climatic change, or hypnotic suggestion." and so on to an extent which one would imagine paralyzing to the credulities of ordinarily sane individuals. It may be added that the learned Judge Ewing was foxily careful to avoid direct explanations of his belief, or to touch otherwise than lightly upon the myriad of conflicting points between Eddyism and pathological physiology. Arbitrary statements, dressed in noncommittal phraseology, served his purposes nicely.

Sidewalk Sales of Medicinal Herbs and Plants — At the last meeting of the Pharmaceutical Society of the Philadelphia College of Pharmacy, held December 19th, Dr. Charles H. LaWall gave an interesting and surprising account of the widespread vending of medicinal herbs and the drugs prepared from them by sidewalk merchants and itinerant fakirs, chiefly in the poorer sections of town. The statement was made that in Philadelphia more than 75 per cent. of the efficient drugs in the Pharmacopœia are obtained from herbs growing naturally in the immediately adjacent county, and that more than 50 per cent. of these drugs are offered for sale on the streets throughout the year. The principal venders are the negroes who live in nearby parts of New Jersey, who not only gather the plants and herbs which grow wild in their neighborhood, but elaborately cultivate them in their gardens. In all, out of 69 drugs of the official Pharmacopœia that are indigenous to this vicinity Dr. La Wall found that 47 were being habitually offered for sale by these people. Of the drugs not included as officinal in the Pharmacopœia, 45 were found for sale, besides 45 different kinds of flowers and ferns reputed to possess medicinal virtues.

MISCELLANEOUS

A Case of Plague in England.—The Peninsula and Oriental Line steamer "Ballarat," from Calcutta, arrived at Plymouth, England, December 16th, with a native Indian fireman on board suffering from the bubonic plague.

"Osteopaths" Not Wanted in Georgia.—Governor Candler, after a conference with many physicians, vetoed on December 21st a bill which had been passed by both houses of the General Assembly, providing for the practice of osteopathy in the State of Georgia. The veto was based on the fact that "osteopaths" know nothing of materia medica, while they would have been given the right by the terms of the bill to prescribe medicine the same as any regular licensed physician.

Scarcity of Military Hospitals in England.—The Government has ordered the Military Convalescent Hospital at Devonport to prepare 150 beds for the next detachment which is expected shortly. Owing to the inadequate supply of Government hospitals various convalescent homes and sanatoria in different parts of England, but especially along the south coast, have generously placed wards and in some cases their entire accommodations at the disposal of the Government for the returning wounded and invalided.

Return of the Sick and Wounded Soldiers to England.—The first detachment of wounded and invalid soldiers from South Africa came up the Thames a few days ago, most of the men declaring themselves almost well again

after their voyage and eager to get back to the Cape. By the odd perversity which often marks human affairs, almost the only serious cases were a few of dysentery and the results of accidents, nearly all the wounded, suffering from what are generally regarded as the real and chief risks of war, being in a rapidly convalescent condition.

The Hospital Ship "Maine."—The American hospital ship, having received every honor and compliment which could be showered upon it, from a most handsomely appreciative cartoon in *Punch* to a reception by the Queen, finished its blaze of glory by a grand theatrical benefit presided over by the Prince and Princess of Wales (the proceeds were divided between the two now famous ships) and sailed for Capetown December 23d. Such was the tremendous rush for tickets *at five dollars each*, to view the "Maine" on the Sunday before she started that the committee had to use the newspapers to acknowledge the receipt of the checks and assure applicants that their tickets would be sent in due time.

LITERARY NOTES.

WASHINGTON'S DEATH AND HIS DOCTORS.

IN the December number of *Lippincott's Magazine* Dr. Solomon Solis Cohen discusses this interesting question, so timely just now, as it is exactly one hundred years since Washington's death occurred. The author of a recent work on Washington which has attracted a good deal of attention, says: "There can be scarcely a doubt that the treatment of Washington's last illness by the doctors was little short of murder." Dr. Cohen takes up the task of showing that this blunt expression of opinion is entirely uncalled for. The treatment adopted by the physicians in the case, the bleedings, purging, and the use of such depressant drugs as tartar emetic were calculated perhaps to do the patient harm rather than good, but this was the fault of the times rather than of the medical men. The true nature of Washington's fatal malady seems to been been properly diagnosed. Death resulted from *cynanche trachealis*, which the attending physicians, Drs. Craik, Dick, and Brown render into English as "inflammation of the upper part of the windpipe."

The symptoms of the case point to the fact that the real cause of death was acute edematous laryngitis. The mistake in the location of the lesion, placing it in the windpipe instead of the larynx, was, as pointed out by Dr. Cohen, probably much more the difference of nomenclature than any absolute error of diagnosis. Even in our day these cases often prove fatal. As late as 1852, in a series of 213 cases of acute edematous laryngitis, Sestier reported 158 deaths. Tracheotomy had been performed thirty times. Of 41 cases reported in 1898 to the American Laryngological Association all the cases, it was said, that had been recorded in the world's medical literature of the preceding ten years, only 29 recovered, tracheotomy having been performed seven times with six recoveries. As Dr. Cohen points out, rarely is the effusion simply serous, but in a number of cases is in part purulent. That there was a septic element in Washington's case, the severe chill with which the disease is reported to have begun seems to indicate.

Dr. Cohen attributes autoscopy to Dr. Kirstein of Vienna. Dr. Kirstein is and has always been at Berlin. He lectures on the subject of laryngology with special attention to autoscopy in Professor Senator's Polyclinic in that city.

THE AUTOBIOGRAPHY OF A QUACK.

The first two instalments of Dr. S. Weir Mitchell's new novel under this title have appeared in the November and December *Century*. It will prove, we think, very interesting reading to members of the profession generally. Some of the touches of nature in the book are most happy. The quack's regret for not having asked a larger fee for impersonating the coroner in a suspicious case, and then for having neglected the opportunity to demand a fee of the friend who insisted on having the autopsy made, is very good.

At the beginning of the second instalment (December *Century*), the quack's defense of himself to himself, is put, as he says himself, in a "rather neat phrase." "I prefer to distribute pecuniary suffering among many, rather than to concentrate it on myself." The quack's appreciation of the possibilities of electricity in his special line are thoroughly amusing and will awaken a sympathetic cord in many minds.

THE PLAGUE AND THE MAGAZINES.

The plague is attracting so much general attention that a number of special articles with regard to it have appeared in the magazines during the last two months. Of these the two most important contributions are the articles on "The Plague at Oporto," in the *Nineteenth Century* for November, and Julian Ralph's article in the December number of *Harper's Monthly*, called "Under the Vulture's Wings," which is really a picture of the present condition of Bombay in India. The sanitary conditions of Oporto as reported by the writer in the *Nineteenth Century* are not calculated to allay fears regarding the continuance of the city as a focus of plague. The death-rate of Oporto for 1898 was 30.6 per thousand, the hightest death-rate in Europe, higher even than many of the small towns usually considered so unsanitary along the Italian coast of the Mediterranean. The infant mortality at Oporto is 226.3 per thousand as compared to 158 in London and 118 in Paris. While in density of population the city in general does not seem to have an excessive ratio, the number being sixteen per acre, in certain parts of the town, in the slums, the density is said to be at least 400 per acre. Medieval sanitary conditions prevail to a large extent. The sewage system is imperfect, the water-supply not properly guarded and natural springs, easily open to contamination from surface as well as underground drainage, are used very commonly for drinking water. Oporto is beautifully situated and the slope of the rising ground gives magnificent opportunities for perfect sewerage, but all opportunities have been neglected. In the central portions of the city,

streets are narrow, scarely more than footpaths, houses have very little light, and no great care is taken to provide windows for the admission of even what light there may be. People sleep in rooms in which the sunlight never penetrates. These quarters are damp, foul-smelling with open latrines in the rooms, and rotting boards and any number of rats as companions. The conclusion is "that there is not the remotest chance of the plague being stamped out." The sanitary cordon was a mistake, the attempts at isolation of the disease, an utter failure.

Julian Ralph in *Harper's* says: "There are two Bombays just now. There will be two during the twenty or fifty years that the plague may last—Bombay the Rainbow City, and Bombay the Horrible. The latter phase is now uppermost. While the plague lasts Bombay must continue dark and hideous, shaded by the vulture wings of death, tainted in water, soil, air, and food, with the bacilli of the pestilence, strewn with dead like a battle-field whereon hunger, filth, and fatalism join hands with epidemic to decimate the human swarm. The picture of fatalistic nonchalance on the part of the natives drawn by Mr. Ralph gives a good idea of the reason why the plague has spread, is spreading and will continue to spread in India, until the British Government in India is aroused to a sense of its responsibility to the civilized world to adopt the most radical measures for its eradication.

CLAUDE BERNARD AND COUNTER-PRESCRIBING AMONG THE PHARMACISTS IN HIS DAY.

A series of articles of especial interest to those who contemplate a medical pilgrimage to Paris next year have just appeared in the French magazine, *Le Correspondent*. The title is "Physicians, as Members of the French Acaddedy." The last physician who was a member of the Academy was Claude Bernard. An amusing incident is told of certain pharmaceutical methods in vogue in his day, which years after formed the motive for his investigation into the physiological effects of drugs. As a young man Claude Bernard served an apprenticeship to a druggist in the small country town in which he was born. Whenever any drug became deteriorated from age, or whenever a prescription was spoiled by some wrong ingredient being put into it inadvertently, or whenever tinctures and other such preparations failed in the making the rule of the shop was *Mettez vous cela de côté pour la Theriaque*! Put that that aside for the Theriaque. The whole heterogeneous collection under this name of "Theriaque" became the favorite medicine for most of the chronic drug-takers in the neighborhood. It was a panacea for every ill and had been known under varying circumstances to cure every affection that flesh is heir to and a few others besides. All this without the printer's ink, the liberal admixture of which makes such remedies so efficient nowadays. It is scarcely to be wondered at that the young druggist formed the resolution of learning something definite and scientific about the effect of drugs on the human system.

PROFESSIONS FOR BOYS AND HOW TO ENTER THEM.

FAMILY physicians are so often consulted with regard to professions that the sons of their patients may take up, that a recent work of Pechell and Nolan, with an introduction by the present Bishop of Calcutta, the former headmaster of Harrow school, will be of interest. The book is eminently practical in the facts and figures that it gives. Young men are discouraged from entering the medical profession at present, owing to the overcrowding of its ranks. The naive remark is added that there is no profession that suffers more from bad debts. On the contrary, the authors point out that there seems to be room for young men in the dental profession, and they insist that young Englishmen who take up that profession should spend at least a year in study in America. Our own President Thwing, of Western Reserve University, pointed out in *The Independent* not long ago that the dental profession was the only one which a young man might reasonably expect to enter in our day and make his own living at once.

CORRESPONDENCE.

THE SMALL PUPIL.

To the Editor of the MEDICAL NEWS.

DEAR SIR—The teaching is that age makes the pupil small. This is not true. The aged with perfect eyes have pupils nearly as large as the young. Only about one person in a thousand has perfect eyes, for most have far-sightedness, astigmatism or dissimilar eyes. Many have all of these. The near-sighted who have no astigmatism and no dissimilarity in the two eyes are few. These have no change in the pupil as age comes on. The size of the pupil depends almost entirely upon perfection in form and innervation of the eyes. If the pupil is constantly small, the eyes are imperfect and there is astigmatism, dissimilar eyes, or far-sightedness, often all of these. Such troubles can be overcome by proper glasses. If perfectly fitting glasses are worn the pupils of the aged are nearly like those of the young.

Age brings out latent defects, the image blurs, the pupil gets small to improve definition. The finest print can be read through a pin-hole in a dark card even though the print is held close to the eye. The unaided eye can not do this. As age advances the lens loses its softness and the focusing muscle, however strong, can no longer shape the lens to throw perfect images on the retina, so the pupil becomes small to sharpen the images. In youth the lens is so soft and elastic that the focusing muscle can do wonders with it.

The eye, instead of becoming old sooner, probably retains its faculties as late as any of the powers of life. If the eyes are perfect or made so with glasses, age has little effect on them. Until lately the perfect fitting and balancing of the eyes with glasses has not often been accomplished except in the simplest cases.

Eyes with less far-sightedness, near-sightedness or astigmatism than 0.25 D and not more dissimilar than 0.12 D may be considered perfect. Dissimilar eyes of 0.25 D or more are present in about fifty per cent. of persons.

There is astigmatism of 0.5 D or more in about sixty per cent. If there is astigmatism or near-sightedness the eyes are apt to be dissimilar.

NORBURNE B. JENKINS, M.D.

CHICAGO, November 20, 1899.

TRANSACTIONS OF FOREIGN SOCIETIES.

SERUM THERAPEUTICS AND ANTITOXINS—INFECTIVITY OF MALIGNANT GROWTHS — LOCKJAW FROM PERIOSTITIS—SUCCESSFUL TREPHINING FOR CEREBELLAR TUMORS–ACTINOMYCOSIS CURED—UPWARD DILATATION OF THE STOMACH—TRANSPERITONEAL NEPHRECTOMY — CONGO SLEEPING-SICKNESS—TUBERCULOSIS OF THE PELVIC ORGANS IN THE PHTHISICAL—ANESTHETICS AND INSANITY — BREHMER'S TREATMENT OF TUBERCULOSIS—BLOOD EXAMINATION IN GENERAL DISEASES.

AT the meeting of the Medical Society, October 9th, HERON opened a discussion on serum-therapy and antitoxin treatment. He administered the old tuberculin to a number of phthisical patients, some of whom were permanently benefited for at least six years. With the new tuberculin the results were more satisfactory, many of the patients having improved in health to a remarkable degree. One patient having lupus did extremely well under the treatment and the scar-tissue appeared perfectly healthy eighteen months later.

WASHBOURN spoke of antistreptococcic and antipneumonic serum. These remedies have no effect on toxins but are antibacterial. In this respect they differ from diphtheria serum which is an antitoxin. Antistreptococcic and antipneumonic serum do not protect against all varieties of these cocci; therefore some patients will be benefited by their use whereas others will not. If no improvement follows the first injections, it is well to repeat them, using a different preparation.

At the meeting on October 23d, SMITH and WASHBOURN communicated a paper on the infectivity of malignant growths. Their experiments showed that embryonic cells when transplanted are capable of limited multiplication. This fact lends some support to the theory of Cohnheim. Both injury and chronic irritation are to be considered only as predisposing causes of cancer just as they may be of tubercle. The authors cited a number of instances of accidental inoculation in the same individual of the pre-existing growth, and insisted on the possibility of re-infection through operation. There is also good evidence of the inoculation of one individual from another. The geographical distribution of cancer supports the theory that cancer is infective. It has not been satisfactorily transplanted from human beings to animals, but there is good evidence that it was transplanted from one individual of the same species to another. General tuberculosis and general sarcomatosis were compared. In both diseases there is late infection of glands and marked cachexia, and both may arise from local irritation or injury. The nature of the bodies found in cancerous cells is still doubtful. They bear a certain resemblance to protozoa in the animal kingdom and to blastomycetes in the vegetable kingdom. It is difficult to explain why secondary deposits are of the same nature as the primary tumor, and the authors suggested that both the parasitic and the epithelial cells are conveyed to distant parts, and in the new situation the former causes a proliferation of the latter. It is at least possible that the bodies found in cancer are the cause of the disease, although the evidence which directly associates the two is wanting.

At the meeting of November 13th, EWART exhibited a case of persistent lock-jaw occurring in a man aged forty-seven who had lost all his teeth. The illness began with a severe cold and one week later, during the night, the lock-jaw set in quite suddenly. He was awakened by a feeling of suffocation due to the closure of his lips unsupported by teeth. Speech, respiration and alimentation were much impeded but there was no true tetanus. This condition persisted for five weeks. There was a tender and slightly swollen spot at the left posterior extremity of the lower jaw, and a diagnosis of reflex spasm due to periosteal irritation was made. After various local applications had failed to relieve the condition, the surgeon made a long incision through the gum over the tender spot and the symptoms rapidly disappeared. It is interesting to notice that the patient had neither teeth nor stumps in his head.

At the Clinical Society, October 27th, GUTHRIE and COLLIER showed a case of cerebellar tumor successfully treated by trephining and drainage. The patient was a boy aged nine years. When three years old he had a fall on his head followed by profuse epistaxis. Four years afterward severe headaches came on and grew worse, being accompanied by drowsiness, yawning, and unsteadiness of gait. Finally operative relief was sought. At that time the walk was typically cerebellar, the movements of the right arm were ataxic and there was evidence of double optic neuritis. At the first operation the left lobe of the cerebellum was exposed. Three days later a trocar and cannula were thrust upward and forward and there was withdrawn about one ounce of clear yellow, highly albuminous fluid which would not reduce Fehling's solution. It could not, therefore, be cerebrospinal fluid. The patient made a good recovery and up to eighteen months later there had been no recurrence of the symptoms, but the patient remained absolutely blind.

TURNER showed a case of actinomycosis in process of cure. The disease showed itself in the right cheek of a man aged forty-two years. Incisions were made into the supposed abscess and in the thin, seropurulent fluid which was discharged through the sinuses thus formed, a ray-fungus was discovered. The sinuses were repeatedly scraped and the patient was given 15 grains of iodid of potassium three times a day.

SLATER, who studied the bacteriology of the above case with great thoroughness, came to the conclusion that the organism was a streptothrix differing from the ordinary actinomycosis bovis and resembling the many streptothrix organisms which can give the same clinical symptoms as actinomycosis.

EWART showed two cases of upward dilatation of the stomach. The symptoms complained of were an ill-de-

fined feeling of malaise together with impairment of the respiration and heart-action. Much exercise in both cases brought on severe anginoid seizures. In both cases the precardial region was encroached upon by stomach resonance which, in one instance, rose as high as the left nipple. Both patients improved under respiratory exercise.

At the meeting of November 10th, SUTTON related the details of a case of primary nephrectomy for rupture of the kidney. This operation has been performed less frequently than it should have been, the diagnosis unfortunately being usually made at autopsy. Evidences of rupture of the kidney are three-fold: First, there is a history of injury in the loin. Secondly, there is an ill-defined lumbar swelling, and, thirdly, there is usually blood in the urine. SUTTON said he had been accustomed previously to attack the kidney through a lumbar incision, but that he had gradually come around to Thornton's transperitoneal method. He had chosen this route in twenty-five cases and the results were excellent. With a little care the peritoneum can be brought together so as to shut in the general peritoneal cavity, while the drainage is more convenient than that through the loin.

At the Pathological Society, October 17th, MANSON read a paper on the Congo sleeping-sickness. So far as known this disease is limited to a part of the Gold Coast of West Africa. It has remarkable latency, said to be as long as seven years. He had known of one instance in which a negro three years after he had left the Congo developed the disease in England. The onset is very insidious. There are gradually increasing languor and muscular weakness, a tendency to sleep, tacitiurnity of disposition, and slowness of movement. The temperature is subnormal with occasional fever. The second period is marked by great drowsiness and prostration. If aroused the patient will reply and eat, but will sleep almost continuously if left alone. In the third stage there are bed-sores and convulsions supervene. There is chronic lymphangitis and sometime a papular eruption with great itching. Death may occur from exhaustion or from some intercurrent disease. A fatal issue is sure although the patient may rally for a time. The etiology is very uncertain although it has generally been assumed that the sickness is of parasitic origin and it is claimed that a micro-organism has been found which bears an etiologic relation to the disease.

At the Obstetrical Society on November 1st, TURNER spoke of tuberculosis of the Fallopian tube and uterus. He examined the genital organs in twenty-seven consecutive cases of tuberculosis in the female. The results demonstrated the frequency of tubercular lesions in these organs in cases of phthisis, lesions of the tubes or uterus or both being found in five subjects, 18½ per cent. He inferred that the usual form of tubercular salpingitis is due to the entrance of bacilli into the open ends of the tubes from the endometrium, although infection through the blood-channels probably also occurs.

At the Society of Anesthetics on November 3d, SAVAGE read a paper on the relationship between the use of anesthetics and insanity. Anesthetics rarely produce insanity except in patients who have previously had attacks of insanity or who are predisposed to it by exhaustion or allied states. Therefore the administration of anesthetics to patients who are subject to recurring attacks of insanity is associated with considerable danger. There is little or no danger to be anticipated from their administration to those already insane. Success has not followed attempts to treat insanity by the administration of anesthetics. Maniacal patients are quiet for a time but return immediately to their maniacal state as soon as the anesthetic is discontinued. Sleep thus produced is temporary and of but little service.

At the Royal Medical and Chirurgical Society, November 14th, FOWLER opened a discussion on the open-air treatment of tuberculosis. Brehmer was the first to systematize this treatment. His principles are: (1) the residence of the patient in the sanatorium under constant medical supervision; (2) complete freedom from excitement of all kinds; (3) a life spent in the open air; (4) rest during the periods of the disease attended by fever. (5) methodical hill-climbing as an exercise when fever is absent; (6) abundant dietary in which vegetables occupy a prominent place, and (7) various therapeutic measures. His program has been variously modified by different physicians to the loss rather than the gain of the patient. Thus to stuff a patient with food and to cause him to lie in the open air, instead of exercising, may make him stout but at the same time make him flabby and incapable of exercise. Many of the Continental so-called "sanatoria" are nothing but huge hotels in which patients are insufficiently observed. It must not be forgotten that the greater amount of food taken, the less significance is to be attached to a gain in weight as an evidence of the arrest of the disease.

ALLBUTT insisted on the difference between lying in a room with a strong draft and lying out of doors. In the former situation one is very apt to take cold; in the latter rarely.

At the Edinburgh Medico-Chirurgical Society, November 1st, GULLAND read a paper on the importance of the examination of blood in doubtful cases of disease, since the blood is the only tissue of the body which may be examined microscopically and chemically during life.

He referred not to diseases such as pernicious anemia or chlorosis, but to general diseases, most of which affect the blood-mixture in some way. In an ordinary blood examination, the number and condition of the red corpuscles and the amount of hemoglobin present, the number of white corpuscles, and the percentage of the different varieties present, the number of blood-plates, and the rapidity of formation of the fibrin network, are the things to be noted. The number and condition of the red corpuscles are of little value in diagnosis, since widely different causes, for instance, gastric cancer or bleeding piles, may produce almost exactly the same anemia. But this examination is of very great value in determining the prognosis in any case. Thus, it is evident that a patient, suffering for example, from pneumonia, has a far better chance of recovery, all other things being equal, if his blood shows five million red corpuscles than if it shows only two million. The percentage of hemoglobin yields

about the same information as the blood-count. The same is true with regard to the rapidity of fibrin-formation. The examination of the white corpuscles is of the greatest assistance. An increase or diminution of the numbers and proportion of the different varieties present, or the presence of varieties not usually found in the blood, may all give information important not only for diagnosis but also for prognosis. Take for example, this case: A woman was confined and the placenta had to be removed manually. Five weeks later the red cells numbered 2,640,000, with 15 per cent. of hemoglobin and a certain amount of poikilocytosis. The leucocytes were 13,400 and mostly polynuclear while the fibrin was increased. Pernicious anemia was therefore out of the question. While this blood examination pointed to an inflammatory condition, the case was reported as probably one of sepsis as it proved to be at autopsy. Leucocytosis is just as important to the surgeon as to the physician. If the blood of a patient suffering from appendicitis be examined day by day an increasing leucocytosis will give warning of pus formation before the temperature or physical examination indicates its presence. The amount of leucocytosis present in malignant disease is an index of the nature of the growth and the size of the tumor and of the existence or non-existence of metastases. If leucocytosis appears the extirpation of a tumor is evidence of its recurrence.

SOCIETY PROCEEDINGS.

HARVARD MEDICAL SOCIETY OF NEW YORK CITY.

Regular Meeting, held Saturday, October 28, 1899.

The President, Dr. Henry C. Coe, in the Chair.

The paper of the evening was read by Dr. Marcellus Reeves, and was entitled

ELECTRICITY IN MEDICINE.

Dr. Reeves briefly reviewed the history of electricity, and then took up its application to medicine since its introduction, which occurred toward the middle of the last century, in London. The forms of electricity that have been found useful in medicine are static or Franklinic electricity, which has an enormous voltage and a very high amperage; faradic electricity, whose voltage is lower and amperage low; galvanic electricity, whose voltage is low and amperage somewhat higher. It must be borne in mind that the negative spark is always the more irritating, and that it should be used only on cloudy days when it is difficult to obtain proper effects from the positive pole. When the patient is perfectly insulated and is given static electricity the nutrition is improved and the pain relieved. It is especially soothing for those nervous, discomforting conditions which are so hard to reach by any ordinary medical means. If sparks are taken from the patient when in this condition a wheal is often produced and a lesion not unlike a flea-bite. This is at first whitish, showing that there is vasomotor constriction, but later it becomes red, indicating that vasomotor dilatation has taken place.

The indirect spark, which is less irritating than the direct, should be used always except on damp days, when it is difficult to obtain the proper charge of electricity. The electric breeze which is obtained from a charged machine by the use of a pointed electrode is soothing for local irritation. In facial neuralgia, for instance, as well as other localized pains, it often gives excellent results, and often works well for such general conditions as insomnia.

There has been a controversy on the question of priority in using an interrupted electric current, in which the interruptions occur millions to the minute. Certain French electricians have claimed the honor, which is, however, generally conceded to Dr. Morton of this city, and a member of this club.

This current is of great service in electric treatment. It causes contraction of the muscles, but the contraction is painless as compared with the faradic current, and the effect is more diffuse. Patients easily bear currents that cause flexion at the wrist or even at the elbows or shoulders without much complaint. There is a feeling while the current is passing as if the hands and arms were made of cork, so complete is the anesthesia. This current has not, however, been used as generally as its good effects would deserve. It is very efficient in the treatment of such maladies as lumbago, sciatica, and other neuralgias, as well as in chronic rheumatism. It has a specific analgesic effect which makes it useful in most painful conditions. For instance, for ovarian pain it has been used with marked success, while stitches of pelvic pain of uncertain cause, and for which it has been difficult to obtain relief, are often completely overcome. It is far better than either the galvanic or the faradic current in such painful conditions of obscure origin.

In general, electricity is good for most subacute or chronic conditions. Static electricity is not a cure-all, and should not be used indiscriminately, but used with precision and judgment it will relieve pain in a number of chronic affections. It must be used with judgment. In eighty cases of neuritis recently treated by static electricity practically all were much benefited. Lumbago, sciatica, neuralgia, rachialgia, pre-pruritus, chronic synovitis, and chronic bursitis have all been benefited. In locomotor ataxia the patient has been strengthened, and while the ataxia itself has not been ameliorated, he has been rendered free from pain.

The faradic apparatus is readily portable, and so is more frequently used in patients' homes. It produces excellent effect by the stimulation of atrophic muscles, and in general by its tonic effects on the surface of the body. Care should be taken, however, not to subject weakened muscles to prolonged tetanization by the faradic current, as this will do harm rather than good. As a general rule the best number of faradic impulses to allow to pass through a muscle per minute is about thirty. A clock-work arrangement can easily be set up which will accomplish this purpose exactly, and at the same time give equal periods for contraction and repose. This method gives the best results for the stimulation of muscles.

To obtain the galvanic or constant current the Leclanche cell is usually the most satisfactory means available. Forty cells are enough for office work. The street current is sometimes employed for this purpose, but even when regulated very carefully it is always more irritant than that obtained directly from the battery.

Magnetism, even that produced by very large magnets, such as those made of cannon as cores of electromagnets and wound with miles of wire, have produced no appreciable effect on these processes of the human body.

A very interesting feature of electrical action is the electrolytic effect upon human tissues. It undoubtedly retards or causes the reabsorption of such tumors as uterine fibroids. Weis found marked changes in the muscle-cells of frogs as the result of electrolysis, and this undoubtedly is the physical basis of the reported cures in cases of fibroids.

A feature of electrical treatment that is coming into prominence just now is cataphoresis, that is to say, the forcing into the skin by means of an electric current of various remedies which would otherwise be absorbed very slowly and in very small quantities. Plumbago has been forced into the skin by cataphoric action to such a depth that it could not be removed by scrubbing. Cocain can be used very effectively to produce cutaneous anesthesia in this way. When it is combined with guaiacol it is not very easily absorbed, and hence does not produce readily the inconvenience of toxic symptoms. In dentistry cataphoresis has given especially brilliant results.

In the discussion which followed the reading of the paper, DR. COX said that he had seen some brilliant results obtained with electricity in the treatment of sprains. It was more efficient and less painful than massage, and had the advantage of not requiring the services of a skilled attendant. Last year he treated four sprained ankles and one sprained knee in members of the Yale football team with such excellent results that the director of the team expressed his desire to have an electric machine hereafter for the work at New Haven. In sciatica electric treatment often gives prompt and permanent relief from pain. In a recent case of bad double sciatica in a tuberculous patient the result was most striking.

DR. LILIENTHAL spoke of cataphoresis as of the greatest interest in the modern use of electricity in medicine. His attention was first called to its possibilities in the production of local anesthesia in a case in which sensitive dentine had been rendered absolutely anesthetic. Even when the pulp was inflamed perfect anesthesia could be obtained by this method. In using cocain by cataphoresis on the skin he has sometimes had urticaria follow the application when the wheal has disappeared in a few days, with some desquamation. In counter-irritation cataphoresis would seem to be of the greatest value.

DR. POTTER said that he had seen some very excellent results in the electrolysis of fibroid tumors under Dr. Apostoli in Paris. The menstrual disturbances ceased alter the treatment, and the tumors seemed actually to become smaller.

DR. JOSEPH KENEFICK stated that he had been able to cure mycosis of the tonsils, especially that due to the streptothrix buccalis, which produces its lesions mainly on the surface of the mucous membrane by the electrical diffusion of salts over the surface. He has found that the opening of furuncles in the ear, which is one of the most painful of small operations in the whole of minor surgery, can be made absolutely painless by cataphoresis. He makes use of the street current, using two to four milliamperes for ten to fifteen minutes. He has found electrolysis of the greatest benefit in the treatment of strictures of the Eustachian tube. Not infrequently impaired hearing depends on the existence of stricture here, and in this case the results of electrolysis are most brilliant. Patients describe certain bubbling sounds which occurs in their ears, as the new-formed tissue of the stricture melts away in the electrolytic process. In these cases it is very important to use the negative pole, as it is this pole which produces destructive chemical changes.

DR. HUDDLESTON suggested that cataphoresis might be employed to drive antiseptics into the tissue in erysipelas and in other such superficial inflammations.

DR. COE said that some years ago Keith of Scotland gave up the use of the knife for fibroid tumors because he seemed to be able to obtain symptomatic results equivalent to a cure from the use of electricity. It is true the fibroid tumor did not disappear, but pain and hemorrhages were so much lessened that the result was very satisfactory. The same was true, to a certain degree, for pelvic conditions in general. Of late years, however, we have heard less and less of this method of treatment, and there are but very few now who continue to employ it to any extent or to express satisfaction with its result.

In conclusion, DR. REEVES said that Professor Apostoli of Paris used to claim that he cured fibroids by electrolytic methods, but faith in the cure in which, it is probable, suggestion played an important rôle, seems to have recently diminished. But enough actual good was accomplished by the electrical treatment to make it unfortunate that the method should not continue to be used, as it involves absolutely no risk and in certain cases is it least as effective as surgical intervention.

DR. WILCOX said that in two cases of rheumatoid arthritis in which the Tallman method of treatment by means of local superheated baths had been a failure, he had recommended the cases to Dr. Reeves for treatment by cataphoresis. In one of the cases considerable success was obtained. Movement was much increased, pain was lessened, and the progress of the disease seemed to be checked. In the other case not much, if any, benefit has been attained as yet. In a case of gonorrheal arthritis he has seen hydriodic acid used by cataphoresis do considerable good; in another case no benefit resulted.

THE NEW YORK ACADEMY OF MEDICINE.—SECTION ON ORTHOPEDIC SURGERY.

Regular Meeting, Held Friday, October 20, 1889.

THE Chairman, DR. A. B. JUDSON, in the Chair.

The first paper of the evening was read by DR. JUDSON. Its title was

THE PATHOLOGY AND TREATMENT OF WHITE SWELLING OF THE KNEE. (See p. 854 of the present issue of the MEDICAL NEWS.)

DR. G. R. ELLIOT read a paper, entitled:

ERRORS OF DIAGNOSIS WITH REGARD TO WHITE SWELLING OF THE KNEE, AND REPORT OF CASES.

DR. ELLIOT said that it is not hard to diagnose white swelling when the classic picture of that affection is presented. In exceptional cases, however, there may be no pain, no atrophy, no reflex spasm for long periods before the development of any pathological signs. This is especially apt to be the case if the affection is limited to the synovial membranes. Two other affections may be mistaken for tubercular arthritis, One of these is chronic arthritis, non-tubercular in character. A case will illustrate: a young girl fell in the street and hurt her knee; bandages and lotions were applied for a couple of days, and she got out of bed and used her limb, favoring the joint. It continued to be sore, and the muscles of the thigh and calf wasted. Movement caused pain, the skin over the joint became pale and there was something that closely resembled reflex spasm. It did not, however, present the classic features of reflex spasm and proved on careful analysis to be rather an exaggerated resistance to movement. The case looked so much like one of tubercular arthritis of the knee that operation was suggested by the attending surgeon before she was brought to me for consultation.

Firm, moist compresses were applied and the joint was thoroughtly fixed. The swelling rapidly disappeared and massage and gentle motion were provided in order to get rid of the atrophy of muscles. The whole condition gradually improved and the patient says now that this limb is as good as the other. (Operation would inevitably have left her lame for life; and it can readily be understood what a benefit it was to her to be saved from it.)

The possibility of mistaking sarcoma of the knee joint for white swelling is not discussed much in the text books. It is important, however, for delay in making the diagnosis may cost the patient his life. One such case has been recently under my care in consultation practice. The first symptom of the case was pain. This was set down to rheumatism and the treatment for that affection was given absolutely without effect. Swelling of the joint shortly set in, and a New York surgeon diagnosed "white swelling of the knee." The pain continued to be a very prominent feature and any extension of the limb could not be tolerated. In order to make the examination the patient had to be etherized. The normal joint was thirteen inches in circumference, while the abnormal one was thirty-one. A series of bony nodules could be felt all over the tumor and fluctuating areas were easily demonstrated. It was decided at once that operation was not feasible. The symptom that demanded relief was the pain. By opening the large fluctuating areas great relief was afforded. The cystic parts were found filled with a bloody serum containing disintegrated red blood-cells. An excised piece of the tumor examined under the microscope showed abundant round cells of the most maglignant form of sarcoma. There was very little suffering after this palliative measure, but the patient died four weeks later. The first sign of the tumor had been noticed seven months before.

The skin over the tumor when I first saw it was maroon colored. SIR JAMES PAGET says that this always means that the tumor is a myeloid tumor, but in this case it proved to be a cystic, round-cell sarcoma. It should be borne in mind then, that when fixation and extension of a limb give no relief the process is probably not a tubercular one, and may be malignant. Constant pain, especially if of severe character, and not merely occurring in spasms, also points to malignancy. The size is another pathological sign of sarcoma. But to wait for this symptom is practically to condemn the patient to a fatal issue.

DR. W. R. TOWNSEND read a paper on the

OPERATIVE TREATMENT OF WHITE SWELLING OF THE KNEE,

in which he said that the benefits of mechanical treatment precluded the necessity of operation if the case is seen early and is properly treated. Whenever abscesses develop, however, whether they be acute or chronic, they should be opened. If the bone seems affected it should be curetted. A movable joint will nearly always be secured if this is done, while otherwise anchylosis will almost certainly ensue. If an abscess forms in the lower end of the femur or the upper end of the tibia, and does not communicate with the joint it may be evacuated before the joint becomes infected. Such abscesses should not be probed for the slight wall of separation, often composed of soft friable bone, may be broken down and the joint infected. If the joint had become septic it should be freely opened and drained. An incision should be made across the joint in front. Free incision with drainage may save the leg or save life. Of course, in such cases there should be no movement. I have here the temperature chart of a case of sepsis of the knee-joint in which the drop in temperature occurred immediately after amputation. Here life was probably saved by the operation. Where the bone is affected an excision of the joint may be done, or an arthrectomy, sometimes called an erasion, may be performed. The typical excision should never be done in a child, as the leg would become deformed with growth. Other deformities, such as bow-legs and knock-knees follow the operation in children. Sinuses should be stimulated into healing by the use of such drugs as balsam of Peru, alcohol, and the like. The indication is to remove all diseased tissue, that is, to do an arthrectomy if possible, if not, an excision. The more careful our mechanical treatment is the less will operation be required. When an operation is deemed necessary it should be performed at once and thoroughly.

NEW YORK COUNTY MEDICAL SOCIETY.

Stated Meeting, Monday evening, November 27, 1899, Held at the New York Academy of Medicine.

DR. S. O. VANDERPOEL, the retiring president of the

society, introduced Dr. George B. Fowler, the president for the coming year.

DR. FOWLER delivered his inaugural address on

SOME NECESSITIES OF THE HOUR FOR MEDICAL SOCIETIES AND MEDICAL MEN.

In brief he said that it seems too bad that the history of medicine is not more commonly studied since it would act as a decided antidote against the toxin of medical vagaries and as a corrosive of an overweening confidence in methods of treatment that have been tried and found wanting years ago. It is to be regretted also that physicians do not take more general interest in the welfare of the commonwealth and municipality. There is too much withdrawal on the part of physicians from their political duties as citizens. The apathy of the better classes is a standing disgrace. Physicians especially are qualified by their wide interests in humanity to take large, liberal views of political questions, and they should take more interest in public affairs.

A third necessity of the hour for physicians is the keeping up of the dignity of the profession, by the avoidance of suspicious methods and the absolute severance of any relation with the irregulars in medicine. The practice of medicine is not a money-making trade, but one of the learned and honorable professions, and its dignity can be properly kept up only by punctilious scrupulousness on the observance of the most honorable principles.

The paper of the evening was then read by DR. THOMAS S. CULLEN of Johns Hopkins University, Baltimore. Its title was

CANCER OF THE UTERUS AND ITS EARLY DIAGNOSIS.

Dr. Cullen's remarks were illustrated by a very large series of magnificent macroscopic and microscopic pictures of the conditions present in these cases. He began with a series of pictures of the normal uterus and the epithelial structure in its various parts, which give rise to the different forms of cancer—the squamous epithelium of the vaginal portion, the cylindrical glandular epithelium of the cervical portion and the glandular epithelium of the body of the uterus. These give rise to the three kinds of epithelial malignant growth which occur in the uterus. Squamous epithelium not unlike the skin gives rise to a neoplasm which is usually slow in growth and spreads by preference on the surface, only at times penetrating into the depths of the uterine tissue by finger-like processes.

The three parts of the uterus give very different and typical neoplasms. While epithelioma of the cervix and body of the uterus both arise from glands, the glands are very different in the two locations and give rise to characteristic carcinomata comparatively easy of differentiation. With regard to the mucous membrane of the body of the uterus, there has always been considerable controversy. It has been generally thought that it was shed at each menstrual period, but it was shown that while there is a hyperemia of the mucous membrane, it remains intact all during the menstrual period. Under other circumstances, as for instance at different ages, the mucous membrane of the body of the uterus has a very different appearance. In old age for instance, it differs very much from what it is in the child or young woman. These peculiarities of the uterus must be well known in order to avoid certain sources of error in the microscopical diagnosis of cancer. For it is possible to diagnose cancer from scrapings of the uterus at a time when there are no clinical symptoms that would justify a positive diagnosis.

Epithelioma of the vaginal portion gives a very characteristic mushroom or cauliflower mass, with dendritic outgrowths. It may be readily diagnosed by clinical examination even before it breaks down. It takes but very little to cause the mass to break down, and as it is mainly composed of cells, and as each finger-like projection contains a blood-vessel, but very slight irritation is required to make it bleed. These growths are very friable and so do not often retain their characteristic appearance for laboratory examination. At times there is not an outgrowth but root-like ingrowths, and then little plugs may be squeezed out of the cervical tissues by pressure, the plugs consisting of nests of cancer-cells. It must be remembered that the squamous epithelium of the vaginal portion may sometimes extend up into the cervix even as far as the internal os, so that the neoplasm is apparently cervical in localization yet squamous in character. Where the neoplasm burrows deeply into the muscular tissue, its cells replace the muscle and make it very friable. The examiner and the operator must then exercise a great deal of care in manipulations, since it would not be difficult to tear tissue and open up a sloughing abscess, thus infecting the general peritoneal cavity.

One of the most common complications of this form of growth is its pressure upon and consequent interference with the function of the ureters, causing the development of hydro ureter and death from uremia. The growth of the mass may completely close up the uterus and an accumulation of material behind the obstruction may lead to great distention of that organ and thinning of its walls. This accumulated material may become infected with the production of a large abscess. Myoma and carcinoma in the same uterus are not infrequent. Usually the myoma is spared from invasion by the cancerous process, but sometimes it is not.

With reference to cervical growths it must be borne in mind that it is often impossible to make a diagnosis at a stage sufficiently early to justify a favorable prognosis after operation, except by scrapings. Adenocarcinoma of the cervix is the most malignant form of neoplasm in the uterus. Often it will appear to be absolutely localized to cervical tissues and an amputation of the cervix will alone seem necessary. The results of partial operation are, however, very discouraging because of metastases.

Cervical carcinoma gives a very typical microscopical picture. Formerly in these cancers of the cervix, certain clinical symptoms often led to suspicion of the presence of the neoplasm, but not enough to justify operation. It was then usually decided to await developments. After they had come it was too late for radical operation.

It is not difficult to differentiate between inflammatory tissue and carcinomatous growth. The pictures are distinctly different. Occasionally a fold of mucous mem-

brane dips down and so on section gives the appearance of cell-nests below the surface. But in the first place it will be found that all of these cells are about the same size and their nuclei also; while if the columns of cells are followed they will be found to be connected with the superficial layer of the mucous membrane. Dilated cervical glands sometimes are a reason for mistakes of diagnosis. In one such case, where the scrapings pointed surely to the existence of cancer, macroscopic examination of the cervix seemed to indicate that there was none, while dilated glands were easily recognizable. A carcinomatous growth was found, however, higher up, justifying the microscopic diagnosis.

Cancer of the body of the uterus is practically impossible of diagnosis, except by microscopic examination of the scrapings. Myoma of the uterus seems to enhance the tendency to cancerous development.

It is a good practical rule that where hemorrhage or other suspicious symptoms of cancer exist the curette should be used, or a portion of the cervix should be removed and careful examination made of the tissue thus obtained, in order to decide whether cancer is present or not. The diagnosis can be made with absolute certainty. Curettage should be complete even for purposes of examination. Otherwise there is a liability that a neoplasm may be present and yet be missed.

The discussion was opened by DR. PAUL F. MUNDÉ of New York, who said that it was known for a good while that the curette and microscopic examination of the specimens thus obtained would permit of the very early diagnosis of cancer of the uterus. Unfortunately cases do not come soon enough to make this method of very much use. Palliative treatment is indulged in for too long, or symptoms that are decidedly suspicious are looked upon as indicating some merely functional disturbance. General practitioners and the public need to be educated so that certain early symptoms may not be neglected for so long a time as unfortunately they are now. With regard to microscopic diagnosis some personal cases had not proved that it was as certain as claimed. In six cases of irregular hemorrhage in five of which the late Dr. Heitzman, whose ability as a microscopist no one could doubt, announced that malignant tumors, in one case lymphosarcoma, in the others, adenocarcinoma were present. This was nine years ago. A curettement was done in each case and fuming nitric acid was applied. All of the patients are alive and well today. Now either curettement and the application of nitric acid will cure cancer of the uterus or there was no cancer present. Clinical diagnosis is still of the greatest service. Pathognomonic signs are the friability of the tissues of the cervix as the result of the cancerous degeneration and the great tendency to bleeding. Treatment of cancer of the uterus despite the most careful diagnosis has been extremely unsatisfactory. Of a total number of 132 patients under treatment 129 of cancer of the cervix and 3 of the body of the uterus, in only four had the patients come at a time sufficiently early to justify the hope that the operation would be a radical one. Yet in these cases it did not prove to be so. Of 32 cases operated on, the results inclined one to the belief with many operators that the patient's life is never prolonged for more than a few years by any operation for cancer of the uterus, even under the most favorable circumstances.

DR. GILL-WYLIE of New York said: The practical working rule must be in all cases where there is suspicion of the presence of cancer to remove the uterus. It not only does away with the danger as far as is possible, but it relieves the symptoms. Cancer in patients under thirty, he used to think, was unknown, but a recent case with typical cancer of the uterus in an unmarried patient of twenty years of age caused him to change his mind. Despite operation death took place from recurrence shortly after. This seems to be the usual experience, that in the succulent tissues of the young the neoplasm grows very rapidly.

The lives of a large number of patients may be saved, and that there are people alive to-day on whom operations were done for what was surely malignant disease, six, eight, and even ten years ago or more is certain. In order to assure successful operation the diagnosis must be made early. For this microscopic diagnosis is absolutely necessary. For years DR. WELCH, at first while he was here in New York, and later since he has been in Baltimore, has examined the specimens from my cases with excellent judgment. There are certain clinical symptoms that are of very great importance and that the general practitioner especially should bear in mind. If a woman has had her menopause and then after a time begins to bleed, it is extremely probable that cancer is present. If it is more than a year since the last menstruation, then the probability becomes almost a certainty. The longer the intermission the greater is the assurance that cancer is present. If these cases would be sent to us very early they could surely be cured.

DR. HENRY C. COE said: Notwithstanding the advance in uterine surgery operations for cancer of the uterus still remain one of the opprobriums of this branch of modern surgery. Much of this unfortunate feature is due to the fact that cases come too late for operation. Until a foul-smelling discharge sets in palliative treatment is employed and after this it is practically always too late for any hope of a radical operation.

A very interesting feature of irregular hemorrhage from the uterus is the obstinate hyperplasia of the uterine mucous membrane, which causes menorrhagia. This grows again and again despite repeated curettements. I should like to known from Dr. Cullen if he considers this a preliminary stage of cancer of the uterus and whether malignancy develops in these cases later on. With regard to the results of operation for uterine cancer I occupy a middle position between Drs. Wylie and Mundé. While I am not an utter pessimist and think that some cases are radically cured by operation, I known that the cures by no means constitute the majority of the cases. The rule for the surgeon must be in every case of irregular hemorrhage not to allow it to persist, but to investigate its cause and so perhaps be able to nip the neoplasm in the bud.

In closing the discussion DR. CULLEN said: For

cancer of the body of the uterus there are no definite clinical symptoms that can be relied upon. The only hope is in microscopic diagnosis. In the laboratory at Johns Hopkins the specimens from every case that has been operated on since 1893 have been kept. In not a single case has the microscopic diagnosis been at fault. The gynecologists have been keen to detect faulty diagnosis, for sometimes the clinical symptoms have not at all pointed to the fact that a neoplasm existed, but they have failed. With regard to cancers of the body of the uterus the prognosis is very uncertain. Cases that look very unfavorable are sometimes radically cured. The favorable ones sometimes die very soon from recurrence. Cases of cancer of the cervix in young persons are very rare, but still will sometimes be found. Chiari, whose authority is unquestioned, found a case in a girl eight years old. With regard to the cases of recurrent hemorrhage where no cancer exists, there is often a glandular hypertrophy. After a series of curettements the hemorrhage ceases.

The condition in two sisters, one of whom is no longer troubled by menorrhagia, while the other still suffers from it, has been followed with great interest. The microscopic picture of the scrapings in these cases is extremely suggestive. There is a distinct increase of the nuclei in the stroma, but not a sign of malignancy. With regard to the prognosis of cancer of the body of the uterus, it must be remembered that even small nodules give rise to metastases which will lead to recurrence and ultimately to a fatal termination.

Dr. Purdy then gave the authentic details of the case of supposed procurement of abortion which has recently attracted so much attention. The two doctors, of whom Dr. Purdy was one, were so wrongfully accused and put to so much inconvenience, went to the case out of charity at the request of women patients of theirs who asked them to do what they could for the woman. The unwarrantable action of the coroner's physician in causing the arrest of reputable physicians practically without any grounds at all was set forth in its proper light. Dr. Purdy stated that consultation with a lawyer with regard to the question of damages for the injury done him had only resulted in making it clear that such an action could not be successful. He asked whether it was possible that the medical societies of New York would allow our present laws to remain, putting the reputation of every physician at the mercy of any inconsiderate, to use no harsher word, coroner's physician who might care to injure it.

A motion was then adopted referring the matter to the Comitia Minora for investigation as to existing abuses and the legislative remedy therefor.

REVIEWS.

Minor Surgery and Bandaging. By Henry R. Wharton, M.D., Demonstrator of Surgery in the University of Pennsylvania, Surgeon to the Presbyterian Hospital, and the Children's Hospital, etc. Fourth edition. Philadelphia and New York: Lea Brothers & Co., 1899.

The fourth edition of this work has greatly enhanced its value by the addition of a chapter on bacteriology, and by appending a terse description of routine operations that might be exacted of any practitioner. The chapters on anesthesia and fractures are particularly conspicuous for the innovations introduced, yet throughout the book both text and new illustrations manifest a thorough revision, which will go far to widen the sphere of usefulness of this heretofore deservingly popular text-book.

Archives of the Roentgen-Ray. Edited by Thomas Moore, F.R.C.S., Surgeon to the Miller Hospital, and Ernest Payne, M.A., A.I.E.E. Vol. IV., No. 1. Philadelphia: W. B. Saunders, 1899.

Steady progress in clinical skiagraphy, both in practical methods and in the study of underlying principles, as well as an evident widening of its field of usefulness, become manifest on perusal of the latest number of a periodical devoted exclusively to this subject. The high standard established from the first appearance of this publication, then entitled the "Archives of Skiagraphy," has been fully maintained in the interesting matter and excellent press work. The contents include an inquiry into the condition of the styloid process of the ulna in Colle's fracture by J. Lynn Thomas, an analysis of an apparently antagonistic effect of X-rays and daylight upon photographic plates by Norris Woefenden, with shorter articles on the Wehnelt interrupter, methods of localization, and new apparatus. The illustrations are particularly instructive, the plates exceedingly clear and well printed.

Surgery by American Authors. Edited by Roswell Park, A. M., M.D., Professor of the Principles and Practice of Surgery and of Clinical Surgery of the Medical Department of the University of Buffalo. Surgeon to the Buffalo General Hospital, etc. Philadelphia and New York: Lea Brothers & Co., 1899.

This previously comprehensive system of surgery in two volumes has not suffered much in its abridged form, and, if anything, in its present style of one volume it will be more serviceable to medical students and to practising physicians and surgeons as a complete and up to date book of reference. Its strong point must be its main effort in practical surgery, due to the collection of veritable monographs from America's foremost surgeons. That such a system lends itself to the thorough revision of an extensive work is herein evident.

The practical applications of the recent advances in bacteriology and examination of blood receive ample consideration, likewise an entire chapter, illustrated by skiagrams, is devoted to X-ray work. By the addition of many original illustrations and thirty-six excellent colored plates the number of illustrations has been brought up to 625. These commendable features and an additional reduction of price bid fair to make this a very popular treatise on surgery.

ENCYCLOPEDIA MEDICA. Under the General Editorship of CHALMERS WATSON, M.B., M.R.C.P. Ed. Vol. I. Abdomen to Bone. New York: Longmans, Green & Co., 1899.

WERE it not for the faith that begets action, enterprises of this kind would never be carried on. With this, the firs volume, with 579 pages, of a medical encyclopedia, to contain when completed 12 volumes, is begun a systematic alphabetical treatment of the most important medical topics following the general lines of the Encyclopedia Britannica. In a sense this comparison we believe is just, for, as is well known, this English classic treats only the more important topics of general knowledge, leaving to dictionaries or other encyclopedic works the discussion of less important or less widely known matters. The present medical encyclopedia seems to be formed on a similiar plan. The more important subjects of medicine included between Abdomen and Bone are dealt with in a singularly practical and satisfactory manner. Certain differences of opiniona sto what constitutes an important subject will naturally be present for every reader of such a work, thus such topics as acarus, acromatopsia, agaraphobia, albumins, albumoses, alteratives, ameba, auscultation, and anesthesia and analgesia, int their general aspects, are not included, all of which from the present reviewer's point of view could have been added to advantage, and others, interested in different lines of work will find many similar gaps. Such are few, however, if the subject of medicine be viewed from a general standpoint, and we have nothing but unqualified praise for the commercial enterprise that puts such a handy, complete, and authentic reference work in the practitioner's hands. Of the different articles no invidious comparisons need be made, yet we believe that for the most part they are up to the standards of modern medical teaching. T e mechanical execution of the work is excellent. The volume is easily handled and the typography distinct and good sized. Illustrations are few and far between.

INTRODUCTION TO THE OUTLINES OF THE PRINCIPLES OF DIFFERENTIAL DIAGNOSIS, WITH CLINICAL MEMORANDA. By FRED. J. SMITH, M.A., M.D. OXON., F.R.C.P., London. Physician (with care of out-patients) and Senior Pathologist to the London Hospital. New York: The Macmillan Company. London: Macmillan & Co., Ltd., 1899.

THE modesty of the author's title is reflected in his preface in which he says that "very little that is new will be found in the following pages." But his book, nevertheless, has a legitimate excuse for existence even according to his own strict apothegm that in view of the flood of works on medicine and its quasi-special branches that is constantly inundating the hard-worked student and practitioner no addition to it is justifiable unless it either presents something new or a more rational and simpler arrangement of what is old, for he certainly has managed to adequately express in sentences and paragraphs what usually is spread over prolix pages. Recognizing the value of the "deadly parallel" for concisely presenting differential points, especially for pedagogical purposes, he has made his book what is practically an extended series of tables and more than half of the letter press is arranged in this way. In addition to the classical symptoms of each condition the author's wide experience has enabled him in many instances to offer suggestions not the less valuable for being less widely known.

Sections that deserve especial commendation are the introductory chapters on diagnosis in general and the pathology of infection, the discussion of the causes of abdominal pain, and the portions devoted to diseases of the nervous system. But the chapter headed "Urgency Cases" is perhaps the one that will prove most acceptable to the student and young practitioner for the causes and diagnosis of the various forms of coma and convulsions and the symptoms of poisoning from the toxic substances likely to be encountered are brought compactly side by side in the compass of fifteen or twenty pages, and so tersely expressed that a clear understanding of their clinical features is inevitable.

With so much that is worthy of all praise it is to be regretted that the author's style is not always as perspicuous as might be desired, and that in many instances a little more care in the construction of sentences would have made his meaning much clearer.

BACTERIA. Especially as They are Related to the Economy of Nature, to Industrial Processes and to Public Health. By GEORGE NEWMAN, M.D., F.R.S. (Edin.), D.P.H. (Camb.), etc. Demonstrator of Bacteriology, King's College, London. Illustrated. New York: G. P. Putnam's Sons. London: John Murray, 1899.

WHILE the golden prospect of saving ammunition and effort by bringing down two birds at a single shot is equally enticing to gunners of all classes, it is also true that such a hope is seldom realized. And never, perhaps, is disappointment so probable as when the optimistic sportsman endeavors to bag both the layman and specialist by inditing a single volume intended to meet the the widely differing requirements of each. Recognizing this fact, the author wisely disclaims all expectation of a scientific audience and addressing himself to the public has produced a work which admirably serves its purpose of setting forth the present status of bacteriologic knowledge to that large group of readers who, while interested in the advance of science, have not had a technical education. It is, however, both in matter and treatment far above the sort of work ordinarily termed "popular," for even the more intricate and less definite subjects, such as the questions of immunity and infection, the relation of bacteria to health and disease, and methods of technic are carefully and adequately discussed. The chapters on the examination of water-supplies, air, and food-products are well calculated to impress the reader with a sense of the dangers that constantly lurk in his environment, and of the ever-present menace to public health that carelessness in the control of these factors presents. It is daily becoming more evident that the popular understanding of the important relationship between bacteria and hygiene is rapidly growing and the establishment of courses in bacteriology in our higher schools and colleges would be a

great advance toward the attainment of a sanitary millennium. It is more especially for such work, rather than for use in medical colleges, that this would be an eminently suitable text-book. It is bound uniformly with its predecessors in "The Science Series" of which it is the sixth volume, while the imprint of the Knickerbocker Press is sufficient evidence that the illustrations and press work are above criticism.

A TEXT-BOOK OF EMBRYOLOGY FOR STUDENTS OF MEDICINE. By JOHN CLEMENT HEISLER, M.D., Professor of Anatomy in the Medico-Chirurgical College, Philadelphia. With 190 illustrations, 26 in colors. Philadelphia: W. B. Saunders, 1899.

THE subject of embryology as presented to the student in his text-book of anatomy or midwifery is of necessity relegated to a subordinate position, and in the attempt to crowd the whole topic into the meager compass of a few pages such a degree of concentration and ellipsis follows that many of the links necessary to the comprehension of fetal development as a chain of logical events drop out, and the whole becomes a series of disjointed units. So the student after floundering bravely through this morass of apparently incoherent phraseology usually reaches the other side content with having enriched his vocabulary by many polysyllabic appellations but for ever after to be hampered in his work through a lack of an exact knowledge as to the causative agencies and inter-relationships underlying many of the morbid states he is called on to diagnose or treat. It is with the view of filling out this pedagogical hiatus that the author has given us a book which, avoiding the omissions and deficiencies of the mere chapter-or-so devoted to the subject in text-books whose main business is with other branches, and yet smaller than the voluminous comparative embryologies, is just of the right size to fit into the student's curriculum and supply an adequate quantity of information without involving an impossible amount of reading. That he has succeeded in his undertaking will be evident to every one of his readers, and this is a sufficient index of the value of his work. The illustrations, so important a factor in the utility of a text-book on this subject, are remarkably well chosen and reproduced with beautiful clearness; too much cannot be said in praise of them. In his text the author has followed the admirable plan of describing the development of the various systems in chronological order and of making each chapter complete in itself, which although it necessitates some repetitions greatly increases the convenience of the book for reference. The description of the complex changes attending the development of the peritoneum is especially satisfactory as is also the chapter on the important subject of the formation of the genito-urinary organs. In short, the book is written to fill a want which has distinctly existed and which it definitely meets; commendation greater than this it is not possible to give to anything.

THE TREATMENT OF PELVIC INFLAMMATIONS THROUGH THE VAGINA. By WILLIAM R. PRYOR, M.D., Professor of Gynecology, New York Polyclinic. Illustrated. Philadelphia: W. B. Saunders, 1899.

IN this little volume Dr. Pryor reiterates his well-known views on the aggressive treatment of the inflammatory diseases of the pelvis. Beginning with a consideration of the various forms of endometritis, he details his method of treatment in the various conditions. Although all gynecologists may not agree with his practice of opening the sac of Douglas when a curettage is found necessary in puerperal sepsis, there are, no doubt, cases in which even this preliminary, or, better, precautionary measure, is useful and practicable.

"Pelvic Inflammation" is next discussed, and the succeeding chapters are taken up with a review of the various inflammatory processes. A conservative note is occasionally struck in pointing out the treatment in these conditions when operation is impossible for one reason or another. The description of the ablation of the uterus and appendages is very clear and its comprehension aided by some very good drawings. Whether the vaginal route, as Dr. Pryor thinks, *is* in the direction of future work, remains to be seen. Certainly he has contributed no small share to its popularization.

Dr. Pryor is in favor of uterine ablation in peurperal septicemia when streptococci are demonstrated in the discharge, when the uterine walls are necrotic and when a septicemia is present which will not yield to curettage and "cul-de-sac evacuation." He has, undoubtedly, some supporters in this contention; but all gynecologists and obstetricians will not stand by him at the present day.

There are good chapters on after-treatment and several topics cognate to the main one. The book furnishes very interesting reading and deserves a large circulation.

THERAPEUTIC HINTS.

For Amaurosis and Amblyopia.—

1. When due to syphilis or the action of metallic poisons:

℞ Potassii iod. } aa. . . . ʒ ii
Pepsin (scales) }
Aq. . . . . q. s. ad. ℥ iii.

M. Sig. One teaspoonful in water three times daily after eating. Gradually increase the dose.

2. When of uremic or rheumatic origin:

℞ Tab. trit. pilocarpinæ hydrochlor. . gr. $\frac{1}{10}$.

No. X. Sig. One tablet every three hours.

3. When caused by tobacco, alcoholism, chronic metallic poisoning, or when of the so-called "physiological" type:

℞ Tab. trit. strych. sulph. . . gr. $\frac{1}{30}$.

No. C. Sig. One tablet three times a day at first, increasing dose until mild physiological effects of the drug appear. In case of chronic metallic poisoning give in conjunction with iodid of potassium.

For Gastralgia.—

℞ Chloralis hydrat. . . . . gr. xvi
Sodii hyposulph. . . . . gr. xl
Aq. menth. piper. . . . . ℥ i.

M. Sig. One teaspoonful when indicated.—*Hare.*
